She may be moved to a chair for a part of the day, having the liberty of the room. After sitting up for any length of time she should be instructed to take the genupectoral position before lying down. Prescribed exercises for the legs and abdominal muscles are to be taken daily. *The fourth week*—If all goes well, she may leave the room and have the benefits of air and sun. Physical exercises should be continued. The duration of the lying-in period and the degree of freedom to be given the patient after the second week must, however, depend on the character and amount of the lochia, the general progress of her convalescence, and the rate of the uterine involution." (Polak's *Obstetrics.*)

*Care of infant:* "After the cord has been ligated and cut, the eyes should be cleansed with a saturated solution of boric acid, after which, if there is any vaginal discharge from the mother, 1 or 2 drops of a 1 per cent. solution of silver nitrate should be instilled in each eye. The mouth should also be gently cleansed, for which may be used a soft cloth and boiled water. The vernix caseosa should be removed by means of some oily substance. The baby should be bathed in water at 100° F., carefully dried, and the cord dusted with some antiseptic powder. Sponging should be practised for 10 days, after which a full tub-bath at 98° F. should be given daily for 6 months. The temperature may then be reduced to 95° F., and at the end of a year to 90° F. The binder and clothing should be woolen. If the infant's extremities are blue or cold, external heat should be applied. The diapers should be made of flannel, and dusting powders should be used to prevent chafing." (*Pocket Cyclopedia.*)

4. *Parasitic diseases caused by meat insufficiently cooked:* Tapeworm, trichiniasis, echinococcus disease.

5. *The principal pathogenic bacteria found in milk, are:* Staphylococcus pyogenes, bacillus coli communis, bacillus of symptomatic anthrax, bacillus of malignant edema, bacillus typhosus, bacillus of cholera, the bacillus of diphtheria, and bacillus of tuberculosis.

6. *Milk should be tested as to:* Specific gravity, total solids, fat, total ash, quality of the ash, and presence of foreign matter.

7. *Characters of good meat:* "Meat when good and fresh should have a marbled appearance, due to streaks of fat between the bundles of muscle fibers. The color should be bright and not too dark, and the surface of the meat should be glossy and not dull. Beef is always darker than mutton, veal, or pork—chiefly for the reason that sheep, calves, and pigs are bled more freely than oxen at the time of killing. The older the animal, the darker and tougher is the flesh. The connective tissue should be glistening and firm. The diaphragm should be firm, and the abdominal and thoracic parietes should show no evidence of adhesions or standing. The pleura should be intact. The bone-marrow should be set and be light red; the spleen, kidneys, and liver should be regular, of a good red, and without variations in color. Good meat is firm and elastic, and does not pit or crackle on pressure. It is juicy, but not wet; and the juice which adheres to the fingers should be of a bright red color. The fat is hard and dry, but feels greasy. The kidneys, spleen, and liver are firm. All lymphatic glands should be firm. The smell of sound meat is well known and characteristic. In order to test this more efficiently, the meat should be pierced with a clean knife or skewer in the direction of the bone, and the implement smelt immediately upon its withdrawal. Good meat gives an acid reaction with litmus paper. Good meat, when dried upon a water bath, does not lose more than 75 per cent. by weight."

*Characters of bad meat:* "Meat that is bad is often soft and watery, some parts are harder than others, and there may be emphysematous crackling. The fat may be liquid or soft, highly colored or even hemorrhagic. A deep dark purple color is seen in meat when the animal has died without being bled, or when some pulmonary congestion or acute septicemia has affected the animal. The lymphatic glands in bad meat may be enlarged, congested, hemorrhagic, caseating, or calcified. The pleura, peritoneum, or viscera may show evidence of disease such as tuberculosis. Pus may be present between the muscle fibers. The carcass may show signs of emaciation. The odor may be that of putrefaction, and the meat may be alkaline in reaction. In advanced putrefaction the meat may become a greenish tint." (Parkes and Nankivell's *Science of Hygiene.*)

8. *Five hygienic reasons for the destruction of flies:* (1) The prevention of diseases which may be conveyed by flies; (2) the reduction of discomfort and annoyance; (3) the protection of articles of food; (4) the saving of many lives which are now needlessly sacrificed; (5) it makes for cleanliness.

9. *Meat adulteration may consist in:* "(1) Addition of foreign substances reducing, lowering, or injuring the quality of the food. (2) Partial or entire substitution of an inferior substance. (3) Extraction of some of the valuable substance from the meat. (4) Coloring, coating, or otherwise changing the appearance of the food, whereby poor quality is concealed, or it is made to look better than it is. (5) Addition of some foreign substance to 'preserve' it." (Price's *Epitome of Hygiene.*)

10. Each child should have thirty square feet of floor space. The height of the ceiling should be about 12 feet. The window area should be not less than one-fourth of the floor space.

MEDICAL JURISPRUDENCE.

1. *Mortuary law is classified:* (1) The last sickness; (2) the disposal of the dead body; (3) the exhumation of dead bodies, and (4) the determination of the cause of death.

2. *Suggillation* is the name given to the presence of purplish spots found on the most dependent parts of the body after death. *Significance:* It depends partly on the cause of death and is found inside the body as well as on the skin, and must not be mistaken for congestion or for the result of violence. It is a sign of death. The *details of a post-mortem examination* must be sought in a good text book on Pathology or Medical Jurisprudence; a description would take more room than is at our disposal.

3. *The methods employed for the identification of blood-stains* are: Chemical test for blood, spectroscopic analysis of blood, microscopic analysis of blood. The *differentiation between human and animal blood* is based on the size and shape of the red blood corpuscles. When the corpuscles are similar to the human corpuscles, the diagnosis is very difficult.

4. *Four causes of death from wounds:* Shock, hemorrhage, pressure, and injury to a vital organ.

*Punctured and penetrating wounds inflicted during life.* "In the living, signs of hemorrhage from the surface and into the edges of the wound will be found; and if life exists sufficiently long after its infliction, the process of repair may be noted."

*Punctured and penetrating wounds inflicted after death:* "In the dead, the absence of hemorrhage and all signs of repair are the same as in other classes of wounds. In a general way, wounds inflicted ten to twelve hours after death may usually easily be recognized, largely by the absence of hemorrhage and by the absence of signs of repair. Wounds inflicted twelve to fifteen hours before death are easily recognized on account of the presence of these conditions together with those caused by muscular contraction. The line, however, is not so distinct between a wound occurring at the time of death and one which was made within a few moments following it." (Dwight's *Medical Jurisprudence*).

5. *In carbonic acid gas,* the post mortem will show signs of asphyxia, and congestion of the various organs; rigor mortis lasts for a long time.

*In sulphuretted hydrogen gas,* the post mortem will show the blood very fluid and dark; and the odor of sulphuretted hydrogen will be present.

6. *Seven medico-legal forms of pregnancy:* (1) Precocious pregnancy; (2) late pregnancy; (3) false pregnancy; (4) feigned pregnancy; (5) unconscious pregnancy; (6) concealed pregnancy; and (7) pregnancy in the dead.

The uterus is the last organ in the body to be destroyed by putrefaction, and so is available for a considerable time to determine the question of pregnancy.

7. *Conditions warranting the induction of abortion:* (1) Certain pelvic deformities; (2) placenta prævia; (3) pernicious anemia; (4) toxemia of pregnancy; (5) habitual death of the fetus toward the end of pregnancy; (6) hydatiform mole; (7) habitually large fetal head.

The physician should call in consultation some specialist or other physician in good standing, and secure the consent of the woman or of her husband or guardian.

8. *The two important questions* are those of civil responsibility and criminal responsibility.

*Intellectual insanity:* "This term means those forms which are characterized by delusions and hallucinations, and which are or may be considered as forms of disease."

*Moral insanity:* "By moral insanity is meant a condition of mind, whether due to accident, disease, or lack of development, associated with a blunting of the moral perceptions, and an inability, in a rational or normal way, to judge on questions of right and wrong." (Dwight's *Jurisprudence.*)

9. *Four classes of monomania:* (1) *Pyromania,* a morbid propensity to set fire to buildings or objects; (2) *Kleptomania,* a morbid propensity to steal; (3) *Dipsomania,* a morbid desire to partake of alcoholic liquors; (4)

(4) *Suicidal mania*, an unaccountable desire to commit suicide.

10. *Material concealment* is the concealment of something which might have modified the terms of the contract or caused the refusal of a contract if such concealment had not existed.

*Relation of suicide to life insurance:* If the insurance has been taken out with the intention of committing suicide and so securing the money for family or friends, the company need not pay; but if the suicide is committed a long time after the issuance of the policy, and it cannot be proved that the insurer intended to defraud the company, the policy will probably be held good and the company will have to pay.

## Books Received.

*The* MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

DIE THERAPIE AN DEN BONNER UNIVERSITÄTSKLINIKEN. Herausgegeben von Prof. Dr. RUDOLF FINKELNBURG. Paper; 614 pages; price 10.60 marks. A. Marcus and E. Webers, Bonn.

MODERNE RADIUM- UND THORIUMTHERAPIE. By Dr. med. ADOLF BICKEL. Paper; price 1 mark; 40 pages. August Hirschwald, Berlin.

OPERATIVE SURGERY. By JOHN J. MCGRATH, M.D. Fourth Revised and Enlarged Edition. Illustrated; cloth; 838 pages; price, $6.00 net. F. A. Davis Company, Philadelphia.

REPORT RELATING TO THE REGISTRATION OF BIRTHS, MARRIAGES AND DEATHS in the Province of Ontario for the Year Ending December 31, 1912. (Being the 43rd Annual Report.) Paper. L. K. Cameron, Toronto.

A TEXT-BOOK OF HISTOLOGY. By F. R. BAILEY, A.M., M.D. Fourth Revised Edition; illustrated; price $3.50 net; cloth; 644 pages. William Wood & Company.

L'ENSEIGNEMENT MÉDICAL À PARIS. 1913-1914. Paper; price 50 centimes; illustrated; 208 pages. Publié par *La Presse Médicale*, Paris.

TRANSACTIONS OF THE AMERICAN SURGICAL ASSOCIATION. Volume 31; cloth; illustrated; 623 pages. William J. Dornan, Philadelphia.

ASSOCIATION OF AMERICAN MEDICAL COLLEGES. Proceedings of the Twenty-third Annual Meeting, held at Chicago, February 26, 1913. Paper; 75 pages.

HOW ANDY MISSED BEING A CRIPPLE. By DOUGLAS C. MCMURTRIE. Paper; illustrated; 15 pages. New York, 1914.

DEPARTMENT OF HEALTH OF THE CITY OF NEW YORK. The Subsequent History of Patients Discharged from Tuberculosis Sanatoria. An Investigation Carried on by the Council of Jewish Women. Paper; 47 pages. Press of Clarence S. Nathan, New York.

ULCER OF THE STOMACH. By CHARLES BOLTON, M.D., D.Sc., F.R.C.P. Cloth; price $4.20 net; illustrated; 396 pages. Longmans, Green & Company, London.

HUMAN ENERGY. By ALBERT ABRAMS, A.M., M.D., LL.D. Paper; illustrated; 53 pages. San Francisco.

TRANSACTIONS OF THE THIRTY-FIFTH ANNUAL MEETING OF THE AMERICAN LARYNGOLOGICAL ASSOCIATION, held at Washington, D. C., May 5, 6, and 7, 1913. Cloth; 323 pages; illustrated. Published by the Association, New York.

GENITOURINARY DISEASES AND SYPHILIS. By EDGAR G. BALLENGER, M.D., assisted by OMAR F. ELDER, M.D. Second Edition Revised. 527 pages; price $5.00 net; illustrated; cloth. E. W. Allen & Company, Atlanta, Ga.

E. MERCK'S ANNUAL REPORT of Recent Advances in Pharmaceutical Chemistry and Therapeutics. Paper; 524 pages. E. Merck, Chemical Works, Darmstadt.

THE PRACTITIONER'S PRACTICAL PRESCRIBER. By D. M. MACDONALD. Cloth; price $1.50; 198 pages. Oxford University Press, New York City.

THE ELEMENTS OF BANDAGING AND THE TREATMENT OF FRACTURES AND DISLOCATIONS. By WILLIAM RANKIN, M.A., M.B., Ch.B. Illustrated; cloth; price $1.50; 116 pages. Oxford University Press, New York.

HYGIENE AND PUBLIC HEALTH. By LOUIS C. PARKES, M.D., D.P.H., and HENRY R. KENWOOD, M.B., F.R.S., D.P.H. Fifth Edition, with illustrations; cloth; price $3.50 net; 736 pages. P. Blakiston's Son & Company, Philadelphia.

## Therapeutic Hints.

**Treatment of Nervous Palpitation.**—Ortner employs in this condition as well as in all cases of neurasthenia associated with cardiac distress, the following:

℞ Iron and quinine citrate, 45 grains.
Strychnine sulphate, 1 grain.
Fluid extract of kola,
Sodium glycerophosphate, āā 6 drams.
Syrup of orange, 7 ounces.

The first four ingredients are dissolved slowly with the aid of heat in the syrup of orange. The dose of this mixture is one teaspoonful three times a day after meals.

**A Snuff for Acute Rhinitis.**—Lieven prescribes the following powder to be used as a snuff for the relief of acute rhinitis:

℞ Magnesium carbonate,
Sodium bicarbonate, āā 2 grams.
Menthol, 0.05 gram.
Phenolphthalein tetraiodide.
Milk sugar, āā 2.5 grams.

**Intensification of Action of Novocain by Means of Potassium Sulphate.**—H. Braun states that Kochmann and Hoffmann have discovered that the anesthetic influence of novocain is greatly increased by the addition of potassium sulphate to the solution of the above substance. Just enough potassium sulphate is added to make a 4 per cent. solution.—*Zentralblatt für Chirurgie.*

**Caffeine as a Heart Stimulant.**—Ortner regards caffeine as a more efficient substitute for digitalis than is either strophanthus, sparteine, or convallaria. He states that in physiological doses caffeine strengthens the heart muscle, expands the coronary vessels, increases the peripheral arterial pressure, quickens the pulse at first and then slows it, and increases diuresis by direct stimulation of the renal epithelium. It is the best substitute for digitalis if the blood pressure is low—never if it is high—and its use is particularly advisable if marked alterations in the heart muscle contraindicate digitalis. It has an effect in the last stage of cardiac insufficiency when all other heart stimulants are useless.

Caffeine is best given in one of its loose double compounds, as caffeine-sodium benzoate, caffeine-sodium cinnamylate, and caffeine-sodium salicylate. As a heart stimulant the dose of any one of these is 10 to 15 grains daily. The following prescription is recommended:

℞ Caffeine-sodium benzoate,
or salicylate ..... 3 grams
Distilled water .....130 grams
Jamaica rum..... 20 grams

Of this solution 1 tablespoonful should be given 3 times a day.

A solution of caffeine is preferable to a powder, as caffeine in the solid form causes in many individuals discomfort or pain in the stomach, nausea, and vomiting.

Caffeine may be administered together with digitalis, as in the following:

℞ Infusion of digitalis.....180 grams
Caffeine-sodium benzoate. 1 gram
Simple syrup..... 15 grams

The dose of this mixture is 1 tablespoonful 3 times a day.

Braun has shown in experiments on animals that caffeine counterbalances the tendency of digitalis to contract the coronary vessels of the heart.

## Original Articles.

### SOME REMARKS CONCERNING CHRONIC DIARRHEA AND CONSTIPATION.

BY ADOLF SCHMIDT, M.D.,

PROFESSOR OF INTERNAL MEDICINE, UNIVERSITY OF HALLE, GERMANY.

OUR conception of chronic intestinal troubles, including those accompanied by diarrhea and those accompanied by constipation, has changed very much during the past ten years. Formerly the two words, "diarrhea" and "obstipation," often indeed mere words, were taken from the anamnesis and were not based upon the evidence of inspection. They filled out the whole symptomatology of the condition; now we try to put in their place as accurate observations as possible regarding the quantity and composition of the feces, their consistency, the frequency of the defecation, etc. Surely one may ascribe the progress of our knowledge in this branch of internal medicine mostly to the careful examination of the feces connected with the use of a uniform test diet, which becomes more and more common in practice. Besides rectoscopy and even to a greater degree the radioscopy of the bowels have contributed a good deal to this branch of medicine.

First, regarding chronic diarrhea, until a short time ago there were only two groups, into which all cases were divided: Chronic enteritis and nervous diarrhea. Nowadays these two provinces are considerably limited in favor of a new group, which may be named "chronic intestinal dyspepsia" or "dystrypsia" (Hemmeter). Within this group we may distinguish several divisions as : (1) The independent intestinal or gastrointestinal dyspepsias, which originate in the gastrointestinal tube itself; (2) the dypsepsias dependant upon the liver or gall bladder, the pancreas, the mesenteric lymph glands or the intestinal vessels; (3) the dyspepsias following the establishment of parasites in the intestines; (4) the dyspepsias connected with troubles of the ductless glands; (5) the anaphylactic intestinal disorders.

But before entering into the details of these different states we must preface some words about their relation to catarrhal or inflammatory diseases of the intestines. We speak of a catarrh if the feces always contain any inflammatory product of the mucous membrane, such as exudated serum, mucus, blood, and pus. In the conditions spoken of chiefly liquid exudation and mucus are in question. As for the mucus, sometimes very small flakes of it, which can scarcely be found with the naked eye, are to be seen in the ground up fecal matter, but these are quite sufficient for the diagnosis of a mild inflammation. Liquid exudation is the principal part of all fluid stools, for there is no reason to sustain the old-fashioned opinion that unabsorbed water of the food passes through the entire intestines. A liquid consistency of the stool without mucus, blood, or pus indicates the mildest degree of irritation of the intestinal walls. Now, in the first place, it must be noticed that all forms of intestinal dyspepsia favor the development of secondary inflammation of the mucous membrane, according to the constant presence of unabsorbed food remaining, with which they are accompanied, and to the consequent growth of bacteria of putrefaction. These catarrhs are sometimes of slow development or appear periodically and disappear early if the patient takes care of his diet; they are seldom severe, do not cause fever, and mostly involve the whole surface of the small and large intestines. On this account, and even more so, on account of the fact that after their disappearance the genuine digestive disorders remain, these catarrhs may be distinguished from the primary inflammations.

The primary inflammations have mostly an infectious or toxic origin. They suddenly set in with fever and severe disturbance of the general health. The dejections are mixed with larger quantities of inflammatory products: mucus, blood, pus, and liquid exudation. Occasionally septic blood infection occurs. The colon is much more involved than the small intestine, even separate parts of it, for instance the sigmoid flexure, may be affected alone. If the small intestine is involved in the process, it gives rise to secondary dyspepsia, which differs from the primary one in a remarkable point; it disturbs at once the absorption of all kinds of food. The course of primary inflammations is as acute as their beginning; seldom they turn into a chronic state and then become dangerous, as, for example, the severe or suppurative form of colitis.

Let us now turn back to the different dyspepsias and the periodical catarrhs occasionally originating from them. The group of independent dyspepsias is almost entirely occupied by the so-called gastrogenous dyspepsia, which is caused by disturbances of gastric digestion and represents not only the most frequent, but also the most important form. Achylia of the stomach is the first under premises to be considered; then follow atony, ptosis, hyperacidity, and other disorders. Though one cannot in this article discuss the different theories of their pathogenesis, it may be said they are all based on the insufficient digestion of the food passing through the pylorus and on the development of the bacteria of putrefaction in the duodenum and the upper part of the ileum. As a rule the gastrogenous dyspepsia begins slowly, remissions and exacerbations occurring from time to time. Except for the abnormal condition of the stool, which is not always liquid, but is perhaps of pulpy consistency and a penetrant odor and which is perhaps produced only once a day, the patients do not complain of pains or other discomfort. They therefore defer a

rational cure as long as possible. But finally the increasing loss of weight or the growing anemic condition demands treatment.

The connection of anemia just mentioned with chronic intestinal dyspepsia has been greatly discussed in the past few years. It is not only a question of secondary anemia, such as accompanies chronic diseases of the lungs, kidneys, and other internal organs, but is even a question of pernicious anemias. It was Hunter, who twenty-five years ago, spoke of the intestinal origin of pernicious anemia, which he supposed to be caused by a specific infection with hemolytic bacteria. Though this suggestion of his could not be proved, a number of facts have since been found which make probable a causal connection between the dyspepsias under discussion and idiopathic anemia. Faber first pointed out that in not less than eleven per cent. of all cases of gastric achylia pernicious anemia is present and in more than eleven per cent. simple anemia with the hemoglobin below fifty per cent is present. As the achylia generally precedes the development of anemia often by a very long period of time—five or ten years or even more—one is justified in concluding that the complication begins as a simple anemia, slowly turning into the disastrous form. My own observations have taught me that Faber's figures considerably increase, if one collects only such cases of achylia as are connected with chronic intestinal troubles, and that such troubles can be found in one-third of all cases of pernicious anemia, for the beginning of the anemia goes up and down with the intensity of dyspepsia and with the general health, but later it becomes progressive and then it cannot be controlled even by a most careful treatment of the intestinal disease. This is not surprising inasmuch as there is more than one factor responsible for the transformation of a simple into a pernicious anemia, namely, the individual constitution, the exhaustion of the bone marrow by chronic irritation, the accumulation of the toxic agent in the spleen, etc. The chronic, but not specific inflammation and degeneration of the mucous membrane in the stomach and intestines leads to a constant absorption of small quantities of hemolytic lipoids, which dissolve the blood cells in the portal venous system.

The treatment of gastrogenous dyspepsia is based on the diet, which cannot be delineated in a few rules. Besides some self-evident rules, such as the most careful mastication of all kinds of food and the avoidance of raw or unsufficiently cooked meat and vegetables, spices, strong alcoholic, sparkling drinks, etc., the composition of the dishes only depends solely upon the condition of the feces, which ought to be examined at least every other day. They alone, not theoretical considerations, can tell one if more carbohydrates (farinaceous or milk food) or more protein (meat, eggs, gelatine) have to be ordered, how much of each has to be taken, etc. Sometimes a sudden changing of the whole regimé proves very useful. Probably the bacterial flora of the intestines cannot so quickly adapt itself to the new conditions. As it is impossible here to go into details, I must restrict myself to these few remarks, emphasizing that a well prepared and reasonably composed diet is the very best medicine with which to combat the disease. Next, if necessary, hydrochloric acid or preparations of pancreas and lavage of the stomach with physiological salt solution or with salicylic acid solution (1:1000) are often indicated, or the duodenal tube may be applied for the purpose of washing out the duodenum or introducing oxygen into it. Hydropathic procedures, such as compresses, douches, also massage, and electricity may extend the scope of the treatment. The drinking of the waters at Carlsbad, Kissingen or Homburg is to be recommended only at the time of remission, if the general behavior is relatively good and the stool is nondiarrheic.

As to the treatment of the other forms of intestinal dyspepsia, it differs only in some subordinate points from the schedule just sketched. In the so-called intestinal fermentation, a singular disease, which is not even frequent, but is rather of theoretical interest, depending on a weakened digestion of cellulose. All kinds of carbohydrates, except a small quantity of sugar, must be avoided for some days, and are afterward, little by little, added again to the diet, until the individual limit of its complete digestion is reached. In secondary dyspepsias following liver or pancreatic troubles, Graves's or Addison's disease, infection with intestinal parasites, etc., we have to treat not only the dyspepsia, but also the original disorder.

Before leaving the subject of chronic diarrheas, one may briefly discuss the chronic mucous, or as it is often called, membranous colitis, a singular state of diarrhea alternating with constipation. The cause and nature of this condition are not yet quite clear, though they have been much discussed in the last twenty years. My own opinion is that a considerable part of this condition arises from unreasonably breaking the original constipation or simple light colitis with irritating enemas, whereas another part starts from or is maintained by diseases of the female organs, and of the kidneys and bladder, by anomalies in the situation of the large intestine by adhesions, chronic appendicitis, etc. On the other hand I cannot agree with the suggestion, especially made by French authors, of a causal connection between arthritism, intestinal gravel, and mucous colitis. I myself have never seen real intestinal gravel appearing in the dejections of these patients, and though I will not deny its existence at all, I cannot help supposing that often the so-called stone cells of pears, which conglomerate and become as hard as sand, and also perhaps the false gallstones (coagulated lime soaps) have been mistaken for real gravel. Of course the etiology of mucous colitis is not always the same, but it always closely depends on nervous conditions, which are often so striking that we might be allowed to speak of it as a manifestation of general nervousness.

The treatment of chronic mucous colitis by means of diet and medicines is only of little value, and the same must be said about cures with mineral water drinking in Plombières, Vichy, Marienbad, Homburg and other bathing places. The use of stringent enemas is rather dangerous. The best results are produced by means of a cautious massage of the bowels, combined with faradization and moderate hydrotherapeutical measures and the use of compresses of mud, etc. Even if massage gives rise to additional pains in the beginning, it should not be stopped, for there is no danger of its causing peritonitis if the presence of chronic appendicitis has been excluded by careful examination.

Chronic mucous colitis must be wholly separated from chronic suppurative or ulcerative colitis, a not frequent but a dangerous disease probably of infectious origin. Out of ten cases of my own observation and about twenty other cases gathered from the literature, only thirty per cent. of the patients recov-

ered, while twenty per cent. died and the rest fell into a chronic disease which made them unable to attend to business or social affairs. Internal treatment consists in systematically applying enemas of disinfectant or stringent remedies, but as this method succeeds only in a small percentage of cases surgical intervention has to be taken into consideration. However, the results of the latter are not certain enough for a general recommendation.

Turning now to the subject of constipation, it is readily apparent how this chapter formerly neglected in medical science, has, by the progress of radioscopy and by chemical investigations of the feces, grown to one of great practical and theoretical interest. Two facts may here be emphasized: First, as proved by myself and my pupils, putrefaction of the fecal matter within the bowels is not, as commonly believed, increased in constipation, but on the contrary, is decreased, and the cause is an exaggerated digestion of the food on account of the cellulose being better dissolved by these patients than by others. The second refers to the varieties of peristalsis revealed by the *x*-rays. From these the authors have derived several types: the ascending type of Hierlin, the hypokinetic type which corresponds to the atonic form of constipation, the hyperkinetic type which corresponds to the spastic form, the hyperdyskinetic type, and lastly the dyschezic type of Hertz. The question which to-day is in the center of discussion is this: Does the retarded movement of the large intestine depend on a primary trouble of peristalsis or must it be regarded as a secondary symptom depending on the composition of the feces? Though the advocates of the latter theory, to whom I myself belong, are to-day in the minority, I cannot declare myself convinced by the facts brought about by the radiologists. We must not forget that radioscopy of the colon makes visible only the retarded movements, but does not explain them. If we rely on the analogous troubles of the stomach, we have learned that almost all functional disorders of gastric peristalsis take their origin from quantitative or qualitative changes in the contents. Primary decrease in the gastric mobility occurs certainly very seldom, even in atonic ptosis, which only favors its development. Why should the colon show other conditions? Why should we here be content with stating that there exists a disturbed peristalsis and not ask for its causes, which at least in the atonic forms are caused by a deficiency of irritation of the wall by the intestinal contents.

But it will not be wise to go too far into theoretical questions. It will be more useful to discuss the practical phases of this subject. Although the just mentioned types of fecal retention in the colon are not sufficient to enable one to distinguish so many varieties of constipation, one form must be considered apart, because its features and treatment differ from the other more common forms; I mean the dyschezia, by which name Hertz understands the impossibility of defecation. The patients affected with it have a normal digestion; their feces are of quite a normal consistence and composition; they reach the rectum within the normal time, but they cannot be evacuated. Sometimes certain mechanical obstacles, as scars, folds, spasm of the sphincters, or weakness of the perineal and bowel muscles, are to be charged, but in other cases there is nothing to be found out and we have to rely on a higher level of defecation reflexes, analogous to the retarded peristalsis of the upper parts of the colon.

On the other hand we are no longer entitled to differentiate atonic and spastic constipation, because almost all forms of constipation go along with intercurrent spasm. Only those cases may be excepted, in which tonic spasm of a single intestinal loop gives rise not only to stopping of the bowels but even to symptoms of ileus—from this we may derive some indications for the treatment of constipation. Although it is often said that one should not give a prescription before carefully studying each single case, one cannot always get a clear conception of it without at least once emptying the bowels. The following is the procedure I have adopted in this class of cases:

First, forbid the patient to take any more purgative and put him on a common mixed diet. If after the last defecation 36 to 48 hours have elapsed, examine the rectum with the finger. If it is entirely filled with large quantities of feces and no obstacle is to be made out, we have to deal with a case of functional dyschezia, which has to be treated by enemas. If the rectum is free, or only small residues of fecal matter are present, order the patient to take twice a day a suppository of a fair amount of extract of belladonna, and to lie down or at least to rest several hours during the day. If he complains of colicky pains, hot compresses must be applied. Now we wait several days without troubling about the complaints of irritability, headache, unclear brain, inability of thinking, etc., which are often made by neurasthenic patients. Only once a day the rectum is again examined. If the feces reach the rectum but are not expelled, the case is to be regarded as a combination of functional obstipation with functional dyschezia. More often, I dare say in the majority of cases, the stool comes by itself in this period of waiting, the mass being in no way hard or thick, but weak or pressed into small cylinders as a sign of spastic complication.

Different from this, the patient afflicted with the atonic form of constipation, if not neurasthenic, often does in no way feel uncomfortable during four, six and eight days or more, though the feces have not yet passed into the rectum. If we now administer a large enema or give a purgative, the patient has a stool consisting of big hard balls, which are generally free from mucus and do not exhibit signs of progressive decomposition.

Of course there are mixed forms depending on the fact that only a very few cases are free from interfering spasms. As to the details of the single case the rectoscopy and radioscopy sometimes were interesting peculiarities.

As regards the treatment spoken of it may be inferred from the above facts that the combination of a mild laxative with the application of small quantities of atropine is in most cases the very best kind of medication. But drugs being not the ideal treatment of constipation we try to dispense with them. The best way to reach this result is indicated by the different branches of physiotherapy which are indicated in all conditions except the mere spastic forms.

It will not be necessary to enumerate all the methods applicable, but I cannot omit mentioning that according to my experience massage is by far the most efficient of them. It should be performed in the beginning by the physician himself. Drinking mineral water in Carlsbad, Kissingen and Marienbad, which is often efficacious during the stay in the place itself, may later on turn out to act in a contrary manner inasmuch as too large doses of

the mineral water have been taken and physiotherapeutical methods have not been combined with them. The purpose of the cure is to increase the stimulus for peristalsis, resulting from the intestinal contents, only to such a degree is is necessary to set free the reflex. By this method and by improving the circulation of blood in the bowels with massage, little by little the balance of innervation, which has been lost, must be restored. Even in the same way the dietetic treatment has to be directed.

One may be surprised that I have not yet spoken of the constipation-diet which for the most patients and also for a large number of physicians is the main point of the whole question. Though I should not hesitate to order the so-called constipation-diet —consisting of vegetables, nuts, fruits, brown bread, and other cellulose-holding substances—in cases showing no spasms I am not convinced of its use, because it generally has already been tried in vain by the patients themselves before calling for our help. It can easily be demonstrated that the power of digesting cellulose is increased in these cases to an astonishing extent. Thus nuts, the peel of apples, pears, and even the chitin-structure of mushrooms, which commonly is indigestible, do not reappear in the stool. This fact must be considered as a constitutionaal factor, not as a pathological one, but as a physiological one. It is the one extreme of the various gift of digesting cellulose, the other being realized in the inclination to intestinal fermentation mentioned above. It is owing to this fact that the intestinal contents of the patients suffering from atonic constipation are digested to such a degree as to leave only small and non-putrefying feces. There is no reason therefore to change the common mixed food. If we will enlarge the quantity of the feces and give them a more pulpy consistence we must rely on such subtances, which in no way can be dissolved and retain their soft consistency while passing the intestines, whether these substances are prepared of liquid paraffine, agar-agar, or similar material. In all cases, where spasms are present, a weak non-irritating food, free from cellulose, should be given.

As to the enemas, the condition in which they are indicated is dyschezia. Of course, if the stool lies in the rectum and cannot be forced out, it is nonsense to give a laxative or a massage of the abdomen. Here enemas of non-irritating substances may be regularly applied every second day without scruple. They work only by mechanically distending the rectum. Besides enemas should be ordered only for the purpose of emptying periodically the colon in primary atonic constipation. In the same manner there act single doses of purgatives, which should not be entirely banished from the treatment. General relaxation of the body often has a good influence not only in removing neurasthenic complications, but also in strengthening the activity of the intestines. Moreover the patients have to be taught to notice the least call for defecation. Although I do not belong to the fanatics of suggestive treatment, I highly esteem the value of instruction and education in all patients suffering from functional constipation.

**Disinfection of the Hands with Iodine.**—M. H. Billet asserts that washing the hands and forearms with a solution of iodine in 2,000 parts of alcohol yields a perfect asepsis without the necessity of any previous scrubbing with soap and water. This procedure may be frequently repeated without giving rise to any irritation of the skin.—*Gazette des Hôpitaux.*

## STIFF AND PAINFUL SHOULDERS.

By H. W. MARSHALL, M.D.,

BOSTON, MASS.

THIS paper includes a short summary of the ideas of several different writers concerning the nature of stiff and painful shoulders, and a review of many details of surgical and orthopedic methods of treatment. It deals also with certain important medical features encountered in the understanding and treatment of these conditions that are abbreviated in most articles. First will be presented compilations of familiar surgical and orthopedic points of view.

A number of surgeons, both orthopedic and general ones, have studied shoulders in the last decade and one of the first names to come to mind is that of Dr. E. A. Codman of Boston, because of his papers upon subdeltoid or subacromial bursitis. In Philadelphia Dr. T. Turner Thomas has described lesions of the capsule of the shoulder joint as causes of stiff and painful shoulders. In Germany Küster has written about subacromial bursitis, while Painter and Baer in the United States have discussed the operative side of the same subject.

Goldthwait of Boston has laid emphasis upon peculiarities of scapulæ as causes of shoulder and back pains, notably flexions at their superior angles, and variations in their coracoid processes. He has pointed out effects resulting sometimes from relaxed muscles in round or stoop shoulder, that the subcoracoid bursa and brachial plexus are likely to be unduly pressed upon in these conditions, giving rise to what is often considered neuritis and rheumatic affections.

In addition to these pathological states just mentioned there remain to be considered infections of the shoulder joint itself—tuberculous, influenzal, gonorrheal arthritis, and allied inflammations; paralysis of the circumflex nerve; tenosynovitis of the biceps tendon; rupture of the supraspinatus tendon; fractures of the humerus; muscular rheumatism; gout; osteoarthritis, atrophic arthritis, and pathological conditions in the region of the vertebral column. All these affections may be causes either of pain or limitation of motion in the arm or shoulder, so that precise diagnosis becomes a matter of considerable difficulty often, or an impossibility at times.

Codman begins one of his papers with the statement that subdeltoid bursitis is by far the most common lesion of the shoulder joint. It has been his experience that more patients seek hospital treatment for lesions involving the subdeltoid, or subacromial bursa, as he prefers to call it, than for all other lesions of the shoulder joint, including tuberculosis and fractures, added together. He believes in those clinics, in which these statements regarding the frequency of bursal lesions are apparently not true, it will be found that these cases are passing unrecognized under diagnosis of brachial neuritis, periarthritis, fibrous ankylosis, gout, rheumatism, and other vague terms. His experience is based upon notes covering more than one hundred cases up to the year 1911; and he has operated upon some of them, demonstrating a thickening of the wall of the bursal sac and the existence of adhesions within it. He believes also that rupture of the supraspinatus tendon frequently is a cause for these symptoms of pain and disability, and reports cases of complete rupture of this ten-

don with successful restoration of function by operation from suturing the separated ends. Finally he has examined dissecting room material, and has demonstrated the not infrequent occurrence of adhesions in the subdeltoid bursæ of cadavers. Furthermore, in examining tendons of supraspinati muscles in dissecting room material he finds evidences of their rupture. In a normal subject the thickness of the tendon of the supraspinatus is uniform when felt between the thumb and forefinger; and where lesions have occurred either through rupture, or from atrophy due to old hypertrophic arthritis, the tendon will be found thin or torn from its attachment. He says he has never found rupture of other rotators in dissecting room subjects unless the adjoining part of the supraspinatus was also torn. And he has found in only two or three instances lesions of the other short rotators of the humerus.

From Codman's work there is no doubt of the frequent existence of subdeltoid bursitis, and the investigations of Painter, Baer, and Küster confirm the most of Codman's observations. At present the points about which questions arise are matters of diagnosis in non-operative cases, and the relative frequency of this lesion as compared with others producing similar symptoms. According to Codman the subacromial bursa is a thin walled closed sac, measuring 2½ inches or more in diameter, attached to the top of the greater tuberosity of the humerus. The office of this bursal sac is to prevent friction between this prominence and the overlying muscular and bony parts. From its attachment at the greater tuberosity, the bursal sac is reflected over the tendon of the supraspinatus and continues up under the acromion and coracoacromial ligament; and then is reflected backward again upon the under side of the acromial process and over the under surface of the deltoid muscle where the latter forms the prominence of the shoulder at the head of the humerus. Finally it returns to its attachment at the tuberosity of the head upon the bony part of the humeral neck. The subcoracoid bursa is between the coracobrachialis and subscapularis, and frequently is a prolongation of the subdeltoid anteriorly, but may be entirely separated, and then it is about the size of a half dollar.

Codman emphasizes the following symptoms and physical signs as occurring at times among the three types of subdeltoid bursitis which he describes. Tenderness localized on the point of the shoulder just below the acromion process and at the outer side of the bicipital groove. Disappearance of this tender point when the arm is abducted in cases which are without adhesions and in which there is not too acute muscle spasm. Limitation of motion of the arm in voluntary abduction or external rotation of humerus upon the scapula in acute and adherent types. He states that approximately ten degrees of motion can often be obtained in rotating the humerus upon the scapula without moving the latter, and that this range of motion is present in cases of subdeltoid bursitis. Pain referred to the point of the shoulder, the insertion of the deltoid, or down the outer side of the arm even to the hand, especially in acute and adherent types. Transitory acute pains, occurring upon abducting and lowering the arm again, when motions are not limited in chronic types without adhesions. He believes the painful catch comes when the tuberosity passes under the acromial process and when the thickened bursal wall is likely to be pinched. There may be irregular catchy movements from roughness of the bursal walls not unlike villous arthritis in other joints. Forward bending of the trunk with the patient in standing posture, until the fingers touch the toes, is possible sometimes in subdeltoid bursitis, he has observed, because gravity then moves the humerus upon the scapula without muscular contraction and therefore does so without pain. This test helps to differentiate between muscle spasm and adhesions in the bursa.

He states that abduction of the arm is impossible when it is hanging at the side, if the supraspinatus tendon is injured. In this position the insertion and origin of the deltoid are so placed that its contraction only forces the head of the humerus upward against the acromion. The supraspinatus first must abduct the arm a little to permit the deltoid to raise the arm, so that the insertion of the deltoid swings out away from the straight line passing through its origin and insertion, and the fulcrum of the lever at the head of the humerus. Atrophy of the spinati is looked for in all cases, and flaccidity of the deltoid on attempted contraction in circumflex paralysis. The *x*-ray may show changes in the bursa when calcification or great thickening has occurred.

Causes of bursitis Codman classifies under traumatic ones which constitute the largest group; infections such as tuberculosis, gonorrhea, and grippe; those cases following fixation of the shoulder after fractures and breast operations, and idiopathic cases.

He divides subacromial bursitis into three clinical groups: (1) Acute or spasmodic type; (2) subacute or adherent type; (3) chronic or nonadherent type.

Thomas deals with stiff and painful shoulders in a different way in the *American Journal of the Medical Sciences*. In his preliminary explanation he defines the one feature that characterizes the cases which he has chosen for discussion as a more or less marked limitation of abduction and rotation in the shoulder joint, never complete, but usually crippling and very persistent. He says in early stages there is always acute pain about the joint, often radiating to the arm, sometimes to the forearm, or even to the hand. There is loss of power in the muscles of the shoulder and arm not readily accounted for entirely by the pain on motion. Indeed, in the later stages there may be little or no pain, although even then usually there will be pain if the restricted motion is forced. When the pain in the shoulder has disappeared, it is frequently found to radiate down the arm, often about the insertion of the deltoid. Scapulohumeral limitation of movement is always present in some degree.

Thomas's conclusions and results are based upon fourteen cases, and also upon experiments with cadavers. He thinks the conditions are due to injuries to the capsule of the shoulder joint upon its axillary side. He points out that in falls and wrenches of the shoulder there is not direct violence usually at the prominent outer aspect, because the individual throws out the arm to break the fall, and in consequence the shock is caught by the abducted upper arm. The resultant strain, he believes, is put mainly upon the axillary part of the capsule. He thinks there are sprains of the joint without actual dislocation, and also cites cases in which very slight causes have produced unrecognized subcoracoid dislocations. One patient dislocated her shoulder while raising her arms above her head in the act of

stretching, and by having the rocking chair in which she was sitting tip suddenly backward. There was considerable pain afterward, but not enough to call a physician. Another patient could not think of any injury, but after an *x*-ray had shown a dislocation she recalled having moved heavy furniture. A third patient fell down two steps, but did not observe that the accident was followed by any decided increase of pain in the shoulder. She previously had suffered from rheumatism, and subsequently was treated for writer's cramps and neuritis before the dislocation was discovered.

Thomas thinks in all cases like this, resulting from greater or smaller injuries, that the torn or injured capsule contracts in healing and limits motion, and that this tendency is increased by allowing the arm to hang naturally at the side in a position of relaxation which favors contracture. He experimented with cadavers, abducted their arms and produced subcoracoid dislocations. He noted that the joint capsule in the axilla was always the first thing to give way, and that considerably more force was needed to actually dislocate it and keep it dislocated. He believes tears in the capsule occur, and that in dislocations at times there may be spontaneous immediate reductions. In abducting the arm under ether in one instance there was a tearing sound such as Codman attributes to breaking adhesions, and in this instance an immediate axillary dislocation occurred. Finally, as most conclusive evidence, he says these same symptoms of contracted capsule have been duplicated in eight patients who have had their joints purposely contracted by operation for recurrent dislocations of the shoulder. Thomas objects to the theory that adhesions in the bursa adone are torn when something is felt to give way with the alarming violence Codman describes, so that one thinks of fracture of the humerus or rupture of the internal lateral ligament of the elbow.

Codman replies to Thomas in a later paper and says: "While I believe that Dr. Thomas's point is well taken, and the lesion he describes accounts for the condition in the minority of the cases, I cannot believe that it is the essential condition in the majority." Codman states that rupture of the supraspinatus tendon also is apt to occur during forced abduction, as he has found by operation after injuries, and in two operations performed for long standing irreducible subcoracoid dislocations.

To the writer of the present paper it seems that both are partly right, and that in severe traumata both sides of the joint are liable to be injured by the thrust of the abducted arm as it breaks the fall. Upon the upper side, the supraspinatus is likely to be pulled from its attachments and injured, as Codman has shown, while simultaneously upon the opposite side of the joint the capsule is likely to be stretched or torn, as there can be no doubt in actual dislocations, and also perhaps in lesser injuries, as Thomas thinks. It seems unwise to place the responsibility too exclusively upon either one of these two involved structures. Furthermore, as the capsule of the shoulder joint is generally found to be a delicate structure, and it is known the joint depends for its strength mainly upon encircling muscles, it seems likely that adhesions in a thickened bursa may be similar in resistance at times to contracted joint capsules.

Goldthwait has studied *variations in forms of scapulæ*, and has associated certain pains about the shoulder, arm, neck, and upper back with their peculiarities. He has shown that in many instances there are forward flexions of superior angles, and that the underlying ribs become irritated in the resultant scraping actions upon them. Abduction of the arm upon the scapula in these cases is free up to the horizontal position, then from this point onward, after humero-scapular motion is complete and both bones move together in rotation of the upper extremity to a vertical extended position, there may be painful sensations referred to the back of the neck, region of the trapezius, and between the scapulæ. These pains will not be confused generally with those due to subdeltoid bursitis, however, because of the free abduction and different localization of the pain. To Goldthwait we are indebted also for recognition of the causes of shoulder pain and stiffness in persons with stoop shoulders. He has pointed to the fact that, when shoulder muscles relax and the weight of the arm sags it downward together with the scapula and clavicle, that the sternoclavicular joint acts as a pivot about which the mass swings. There is in consequence some forward shifting, as well as a direct downward sagging; and the relations between the humerus and coracoid process of the scapula are altered a trifle, the two approaching each other and the interposed subcoracoid bursa as a result becomes more easily pinched. Some individuals possess much longer coracoid processes than others, as Goldthwait has observed, and inflammations of the subcoracoid bursa in these persons are very likely to occur when in addition there also is a stooping attitude. He believes on account of the position of this bursa, and its almost constant use in motions of the shoulder, that it is undoubtedly more often inflamed or affected by violence than any of the other bursæ about the shoulder joint. Codman believes subdeltoid inflammation is most common.

The symptoms and physical signs of subcoracoid bursitis according to Goldthwait are as follows:— during the acute stage of inflammation there will be pain and sensitiveness, with limitation of motion, and there may be entire disappearance of symptoms as inflammation subsides. If adhesions form they may simply limit the motion. Pain is referred to the region of the deltoid or down the arm or along the course of the ulnar nerve, much the same as in subdeltoid bursal affections. Occasionally the whole arm and hand are painful, and associated with this there may be disturbances of circulation, the whole condition appearing like a neuritis. Tenderness may exist just external to the coracoid process. Limitations of arm motions are especially in rotation, both inward and outward. If adhesions have formed there may be practically no rotation in either direction; yet considerable antero-posterior motion of the arm may exist, Golthwait says, about the coracoid process as a center. The humerus accommodates itself to this fixed point and moves in and out of the glenoid cavity until limited by the capsule and bony structures. There may be partial retention of abduction because in this motion there may not be very marked changes in relations taking place between the coracoid process and lesser tuberosity of the humerus.

*Brachial neuralgia* is a condition which has to be differentiated from other lesions, and its diagnosis often is very unsatisfactory. Thomas believes that in injuries to the shoulder there may be extravasation of blood sometimes into the axilla and between

the muscles, which, organizing, may contract about nerves and produce the persistent and variable symptoms often seen. Goldthwait thinks some cases of stoop shoulder with neuritis show the effects of pressure of the head of the humerus upon the brachial plexus beneath. He says the whole axilla shifts a little, and that the relaxed muscles allow the humerus to lie against the nerves beneath. In thin persons especially he believes the posterior branch of the plexus, the ulnar nerve, is likely to get pinched against the second rib, while in fat individuals the pain is more generalized. Codman calls attention to inflammatory septic conditions of the axillary tissues that may lead to contractions of connective tissue about the nerves with resultant brachial neuralgia.

*Inflammations of the shoulder joint* due to infections are relatively rare when compared with other articulations. An acute inflammation in the shoulder, developing without trauma, and following some infection like grippe or urethritis, often can be identified by the history of the case. Insidiously developing lesions should make one suspicious of tuberculosis, although tubercular arthritis of the shoulder joint occurs in only a few per cent. of all cases of articular tuberculosis. The diagnosis generally is not made until the *x*-rays show characteristic bone lesions. Tuberculin reaction may be tried in these obscure instances. Obviously the limitation of motion in tuberculous or infectious arthritis may simulate the limitations seen in bursal inflammations, and there are no very clear differentiating symptoms. Pain on motion and tenderness about the joint are present in lesions of the shoulder joint itself. Codman believes that when no rotation whatever of the humerus on the scapula exists the lesion is within the joint capsule. Pain in the joint transmitted along the humerus by pressure upward on the elbow in such cases also is considered indicative of shoulder joint disease. Practically, the diagnosis often is not made early in these cases, as they give generally some history of slight trauma at least; and are likely to be considered bursal inflammations or traumatic injuries. One such case of tubercular arthritis was manipulated under ether, the patient having a history of a fall from a bicycle. The *x*-ray was negative at the time, but a few months later exhibited characteristic changes of joint tuberculosis.

*Fractures of the tuberosity, and of the anatomical and surgical neck of the humerus.*—These may be confused with bursal inflammations. There may be a tender spot at the prominence of the shoulder, but *x*-rays differentiate them. Such fractures according to Codman nearly always show ecchymosis and swelling down the inner side of the arm. Traumatic bursitis is frequently a late complication of such fractures but at the first examination the bursa may appear normal. Painter has called attention to calcareous deposits in the subdeltoid bursa that may be confused with fractured tuberosity in *x*-ray appearance, and he also states that a thickened bursal sac may cast a shadow of density equal to some calcified bursæ.

*Tenosynovitis of the tendon of the long head of the biceps.*—That inflammation in the tendon sheath occurs occasionally cannot be disputed, as the tendon has been found slightly reddened locally in one instance at least in which the sheath was opened. Its proximity to the subcoracoid and subacromial bursæ make its diagnosis unsatisfactory. Codman calls attention to the fact that rotation of the humerus leads to more extensive slipping of this tendon in its sheath than moderate antero-posterior flexion and extension; and he considers the presence of ten degrees of rotation is much against the presence of inflammation of the sheath. Accurate localization of tenderness over the tendon is about the only sign by which diagnosis can be made. "Glass arm" in base ball players very likely may be due to inflammation in this serous sheath as well as in adjacent bursæ.

*Acromioclavicular arthritis* may be associated with pains in the shoulder when the arm is moved. Localized tenderness at the articulation, and thickening sometimes about the joint fixes the diagnosis.

*Arthritis deformans.*—Osteoarthritis and atrophic arthritis may occur in the shoulder. When the scapula is ankylosed to the humerus and both move together, and there are evidences of the disease in other joints there is no difficulty in diagnosis, but in beginning stages and in absence of involvement of other joints, the diagnosis cannot be made with any certainty. Bony hypertrophic changes as seen in *x*-ray, if of marked degree, fix the diagnosis upon osteoarthritis, but additional infections or toxemic types, it should be recalled, frequently complicate osteoarthritis and are causes of symptoms which are attributed to the former usually under these circumstances.

*Chronic rheumatism* will be discussed under conceptions of stiff and painful shoulders from the standpoint of the medical internist.

*Circumflex nerve paralysis* may occur, according to Oppenheim, after falls and injuries, from compression of the nerve with crutches, and from infections. He states there is a form of lead paralysis limited to the deltoid. Diabetic neuritis also may involve the circumflex nerve alone. Such patients cannot abduct their arms, or at least the supraspinatus can do so only with great difficulty. Examination may show degenerative signs in the deltoid muscle, and there may be disorders of sensation. Codman finds this paralysis relatively quite rare, and recognizes it if present, by the absence of the contraction of the fibers of the deltoid when efforts are made to raise the arm. In atrophied, non-paralyzed deltoids, the muscle can be felt to contract even though motion is not accomplished.

The various ideas which have been reviewed may be summarized by saying that some shoulder troubles present enough data to permit accurate diagnosis, while frequently others, it must be admitted, cannot be differentiated. When there is limitation of motion in abduction and external rotation and the subdeltoid bursa is obviously tender or fluctuant or shows a lesion in *x*-ray examination there is no uncertainty about the nature of the lesion. If there is loss of internal and external rotation of the arm and this is accompanied by stoop shoulders or occupations which roll the shoulder in, and there is tenderness limited to the subcoracoid bursa, there is no doubt as to localization in the subcoracoid bursa. With definite history of subcoracoid dislocation followed by partial disability presumably some of the symptoms may come from the torn capsule. If narrowly limited to the course of the biceps tendon then inflammation of its sheath is a rational diagnosis, while pain further back in the region of the trapezius, associated with scapula crepitus, will fix the cause in abnormalities of the shoulder blade. Neuritis,

muscular rheumatism, gouty and toxemic states are the conditions which confuse the picture, also the combined lesions of capsule, bursæ, and axillary tissues; and in these cases exact unquestionable diagnoses are impossibilities.

In the writings of all the men who have been mentioned the mechanics, surgery and pathology of shoulder troubles have been the main themes. Toxemias, neuritis, idiopathic causes have been mentioned, but they have been relegated to the background, and demonstrable lesions have been dwelt upon at length. It is possible and correct, however, to consider these same traumatic, developmental, postural and pathological types from another entirely distinct standpoint, as representing the results of chemical properties of the blood and the responses of the tissues to chemical and physical stimuli. Everyone who receives a blow, or who falls with abducted arm, does not develop shoulder stiffness although the trauma may be more severe than that received in some cases which have been cited. And certainly chemical and physical properties of the blood are as important as, although apparently more obscure than, anatomical and mechanical considerations. Stiff and painful shoulders will be dealt with briefly from a medical standpoint, therefore; and, as will be shown, it is justifiable to lay emphasis equally upon remote intangible causes. Let readers stop and consider whether it is true or not that orthopedists and surgeons commonly omit exhaustive discussions of medical features, or upon the other hand whether medical internists spend relatively little time upon orthopedic and surgical diseases. And in consequence are not medical treatments of surgical troubles more or less neglected by all? Overwhelming amounts of chemical and bacteriological investigation into specific biochemical reactions of the blood are in progress at present, and these are casting their influence even now over practical clinical work. But apart from foreign bacterial substances and abnormal products from diseased organs, the blood, viewed simply as a soil upon which all tissues grow, also is becoming recognized as a factor of very great moment in all diseases.

Lack of good red blood is an exceedingly important although an obscure cause of stiff and painful shoulders. When it is of otherwise good quality there may be harmful bacteria, or their products, in it which produce their harmful effects upon synovial linings and bursæ, or upon the bones and muscles. When it is impoverished and of inferior quality, but without active bacterial toxins as in adolescence, and mild autointoxications, there are seen drooping round shoulders, loss of muscle tone, and faulty development changes in some of the bones. These are caused directly by simple quantitative variations and abnormalities among the normal vascular constituents. Upon past qualities of the blood, namely, upon absence of foreign irritants and presence for long periods of time of most favorable vascular proportions of normal substances, depend the vital resistances of the various tissues, including the shoulders. If tissues have had good soil to grow upon previously, and are in robust states at the time, they will withstand successfully the accidental falls and blows they encounter. On the other hand, if they have been struggling for a long period to thrive on a barren soil laden with excesses of useless waste products like urates, intestinal bacterial waste substances, or occasional small quantities of active bacterial toxins, they succumb to injuries; and also at other times idiopathically give out with development of rheumatic, neuritic, and arthritic symptoms. It seems utter folly to pass over these vascular states with their variable obscure manifestations, for upon them depend so often the failures of perfectly executed surgical operations, and delays in convalescence from the troubles under discussion.

Blood pressures; relations between renal and cutaneous excretions to digestion and diets; respiratory functions; efficiencies of defensive functions against foci of infection, etc., are matters which orthopedists as well as surgeons and internists must regulate precisely in order to avoid having their best efforts undermined at times by constantly fluctuating blood currents. These are problems of pathological physiology and chemistry, and can be controlled perhaps roughly, but relatively improved often in practice greatly by simple understanding and *application* of a few principles.

These difficulties orthopedists and surgeons have especially to guard against, and there is much truth in an illustration of Dr. Ansel G. Cook of Hartford, Conn., who says, that "in order to fit shoes successfully one must be able to think of 418 different things at the same time. If one thinks of only 417 things and forgets the 418th, and it happens to be the most important (which it usually is), the other things go for nothing and the shoes are a failure." In order to introduce the subject of medical treatments for orthopedic troubles the present ways of treating stiff shoulders will be reviewed briefly.

*Treatments for subdeltoid bursitis* will be reviewed upon the basis of Codman's paper which contains detailed records of twenty-six cases. As these were selected by him as representatives of their special types they illustrate the points to be mentioned best of any data at hand. He thought it advisable in his article to omit descriptions of some uneventful successful acute cases and to include all unfavorable results. He reports two traumatic acute types of few days' duration treated simply by rest with supports and occasional gentle exercises. In both instances recovery followed in two weeks. Twelve cases were of the more severe adherent kind, ranging from six weeks to eight months in duration, averaging four to five months. Two of these were gradually and gently stretched by repeated trials without ether, and recovery resulted in periods respectively of five and twelve months. One adherent case recovered in one year with no treatment except ordinary use of the arm.

The remaining nine were manipulated under an anesthetic to break adhesions, and then were fixed with the arm abducted. In these nine forcibly manipulated ones recovery occurred in three to twelve months, averaging four or five months, the same as those subjected to gradual stretching. One of the nine died six weeks after manipulation with symptoms suggesting thrombosis due to rupture of the axillary vein at operation. Three of the nine, however, showed almost immediate improvement, either in diminution of pain or in increase in motion.

Incision of the bursa was made in seven of the twenty-six cases. Adhesions were either broken under direct observation, or were excised. One of these patients with incision and breaking of adhesions, showed great immediate improvement and completely recovered in six months, a second could use the arm in three weeks and completely recovered in six months, and the third recovered in four months. These results do not differ greatly from the four- or

five-month averages seen in the previously mentioned ones of Codman's series.

Cases diagnosed as due to irregularity in the surface of the bursa, and in which no operation was done, were three of the twenty-six. These all gave subsequent histories of irregular attacks of pain and one of them afterwards became adherent. One of the twenty-six had irregularity of motions without much limitation, and a small spicule of bone was found protruding through the tendon of the supraspinatus. The symptoms were relieved almost immediately after it was clipped off at operation. Two of the twenty-six showed cysts at operation at the base of the bursa, and relief after removal was immediate and permanent.

Codman comments upon the various treatments as follows: In the acute cases the indications are to avoid adhesions and to increase the comfort of the patient. For comfort morphine, phenacetine, bromides, aspirin, etc., are used. For physiological rest of the muscles, the patient may be seated with a table at his side and the abducted arm laid upon a pillow on the latter. At night the patient may lie on his back with abducted arm, and the arm laid upon a pillow which is arranged along its length. A sling may be used cautiously during the day when moving about, but occasionally the arm should be taken out and allowed to swing at the side. A Velpeau bandage should never be used for more than a day or two. Counter irritants are regarded with distrust, but massage applied at non-tender parts about the shoulder are of advantage. In adherent cases treated by rupture of adhesions under an anesthetic there are two objections, namely that normal joint structures may tear more easily than dense bursal adhesions. Codman believes that he has ruptured the supraspinatus muscle in this way at least once. The brachial plexus and axillary vein also are in danger.

The second objection is the reformation of adhesions, and Baer has found that repeated manipulations under ether, as first advised by Putman in 1882, are very trying to patients. Many a patient, he believes, has been brought to the verge of a nervous breakdown by the constant pain which persistent passive motions necessitate. Codman formerly put up his cases in an abduction splint, but now has abandoned this method in favor of Painter's and Baer's way of letting the arm hang at the side. Baer states there are certain cases where the bursa has been transformed by repeated manipulations into fibrous tissue of such thickness that it cannot pass under the coracoacromial ligament. Painter calls attention to the fact that ether has to be given whether operation or manipulation is attempted, and the risk of incision is only the risk of superficial sepsis. The operation is not a long one if the bursa is dissected out, convalescence is much shorter after the open method, and he believes functional results are considerably better than after manipulations.

In his comments upon his own operative cases Codman says that although the records do not show any striking differences from the non-operative ones, yet it is his impression that the former suffered less and obtained actual function sooner, although complete recovery took place in practically the same time as non-operative ones.

Painter thinks manipulations under an anesthetic, followed by frequent passive motions and massage, should be attempted first in all cases which have lasted less than six months. After a longer period than six months he believes operative measures constitute the best course, and cites the cases of two physicians who were able to return to their practices within three weeks of operation.

Cases of subdeltoid bursitis due to irregularity in the surface of the bursa present a very variable prognosis. Many persist for years with periods of exacerbations of symptoms, crepitus, or jerky motions of the shoulder. Some finally subside, and some become eventually acute or adherent, and then require appropriate treatments.

For home treatment in the gradual stretching of adhesions Codman suggests the following five simple directions: (1) While sitting at home keep the elbow raised on the arm of a chair or table as much as possible. (2) Mark the day of the month on the wall as high as possible with the lame arm each day, trying to increase the height from day to day. (3) Stand for five minutes each day with elbow resting on the mantelpiece and feet placed far away, so as to bring the weight of the body partly upon the affected shoulder. (4) Massage and kneading of shoulder muscles daily. (5) Rotation of the arm with cane or broom handle by grasping one end of the stick in the hand of the affected shoulder. If the cane rests in the hollow of the elbow and extends backward, as the forearm is bent at a right angle, any gentle pressure or pull against the posterior end of the stick will tend to rotate the arm outward about the fulcrum of the lever at the outer condyle of the humerus.

*Treatments of lacerated and strained joint capsules:* Thomas says: "If I were treating an ambitious young man who insisted upon attending to his business I would dispense early with fixed abduction, bind the arm at the side, and support the wrist in a sling from the neck. I would remove the dressing daily, and as soon as the pain would permit begin gentle massage and passive motions, gradually increasing the force until the length of the injured portion of the capsule, and therefore the motion, had been increased to the normal. If the patient were a highly nervous and sensitive woman I would advise her to remain in bed, and would then adopt some measure for keeping the arm in full or nearly full abduction. This would permit healing of the injured portion of the capsule at nearly its normal length. If an obtuse angled splint is employed, this may be removed daily, when gentle massage and passive movements could be carried out. At the end of two weeks, or at most three, the arm may be lowered to the side of the body gradually." If the patient will not remain in bed, and is a man, some method of abduction by splint or plaster cast is employed. Thomas quotes Kuster of Germany as applying a plaster cast with arm at the side for eight to fourteen days, and then beginning careful passive movements and baths.

*Treatments for flexed scapulæ, and subcoracoid bursitis:* Goldthwait tries to prevent development of flexed scapulæ in patients of fifteen years or less by means of spring back braces supplemented by exercises for development of trunk and scapular muscles. Readjustments of clothing are made so that undue strain is not placed upon the tip of the shoulders but more upon the base of the neck. Bracing the shoulders back in adults increases the symptoms, and cases of short duration can be temporarily relieved by strapping the shoulder forward, in which position the friction upon the ribs is minimized. Obstinate cases are treated by him by removal of

a part of the superior angle of the scapula. In bursitis limited to the subcoracoid region, strapping the shoulder upward and backward may pull the humerus away from the coracoid process sufficiently to relieve symptoms, provided adhesions do not exist. Adhesions may be broken after a preliminary rest if they are accompanied by acute inflammatory symptoms. The rest allows subsidence of the latter. In describing the details of the manipulation Goldthwait says whether in the subacromial or subcoracoid bursa, either or both, the manipulation is similar.

The arm should first be flexed and extended in the antero-posterior plane as much as possible and should then be raised from the side, one hand grasping the elbow, the other holding the shoulder so that the scapula does not move. After a right angle with the body has been reached the arm should be carried higher and should at the same time rotate outward until when it is vertical it is outwardly rotated to the full, normal amount. After full motion has been obtained in either of these bursal conditions the shoulder should be held fully extended so that the scapula rests upon the ribs at the back, and this can be accomplished best by adhesive plaster strapping. Quiet for a day or two is encouraged with local heat applied in any form. Afterwards the patient is allowed to go about with shoulder held back in good position. Excision of the bursa is advised in obstinate cases. He also states that the end of the coracoid process should be removed when it is noticeably abnormally elongated and after other treatments have failed.

*Other treatments:* Brachial neuritis from pressure of the humerus in stoop shoulders is treated by pulling the sagging arm up and backward, and when accompanied by flexed scapulæ removal of the superior angle of the latter is indicated if the corrected position starts another train of symptoms referable to the angle. Neuritis will be considered further under medical treatments.

Treatment of tuberculous arthritis of the shoulder joint consists in immobilization as soon as the diagnosis is positive, sacrificing motion in the joint afterward if necessary to an attempt to hold the bacterial invasion in check by complete freedom from mechanical irritation, and by attention to personal hygiene. Treatment of circumflex nerve paralysis will not be discussed. Acute infectious arthritis of the shoulder joint of influenzal and other bacterial origins is treated by rest during acute stages, with occasional gentle passive motions and massage as soon as subsidence of pains permits in order to avoid adhesions. Shoulder joint inflammations with adhesions are liable to be confused often with adherent bursal cases, as experience has shown, and moreover the bursæ are very commonly simultaneously involved in these cases. Choice of treatments lies between gradual stretching or in forcible manipulations under ether, or rarely in operations. In one case of mistaken diagnosis in which both shoulder joints were affected, one was manipulated under ether for subacromial bursitis, and there was recovery of both in one year, but the untreated shoulder became normal before the manipulated one.

In view of data like this it seems that vaccine treatments should be tried carefully when definite histories of infections exist.

*Discussion of medical treatments for shoulder cases:* Turning finally to pharmaceutical and internal medical treatments, one is impressed with the stress laid upon mechanical and surgical details in the various opinions which have been mentioned, and the secondary place alloted to pharmacology and internal medicine. In a general way the different writers have mentioned regulation of diets and eliminative functions, general tonic and hygienic measures, and presumably they each recognize the importance of these matters. However, there seems to be a real danger that readers generally will overlook the important influence of internal medical treatments from the preponderance of mechanical and anatomical considerations, and that a tendency will grow toward making treatments more and more mechanical. Therefore to emphasize hygienic features let attention again be turned to the twenty-four chronic or subacute cases recorded by Codman. His records are so unusually complete that it is possible to observe among them that there are seven with debility, anemia, and run down states; that only ten healthy individuals had histories of very definite severe traumata; while thirteen cases were without pronounced injuries and with insidious or abrupt onsets as seen in infections and metabolic disturbances of other joints.

Of these thirteen non-traumatic cases one occurred in adolescence; one had a history of a felon; one had had grippe previously; one presented a hypertrophic spicule; one was a heavy plethoric individual; one had a rheumatic history; one apparently was an occupational affair due to repeated slight frictions; one had had "gastric fever," nephritis, etc.; two were insidious without obvious infections or traumata and the patients were in apparently good health at the time of onset. Analysis further is not very profitable because much depends upon the definition of recovery, whether complete motion, or complete cessation of pain, or both, or whether arms which are simply useful and functionating normally in ordinary activities are meant by this term. These statistics show very conclusively, however, that traumata and mechanical features are not any more important than vascular causes, only ten of the twenty-four occurring as the results of decided traumata in these severe types. Debility, anemia, infections, poor physical development, rheumatic tendencies, plethoric states, hypertrophic processes, etc., attest the equal importance of vascular peculiarities and causes.

*If more than half of all severe cases of subdeltoid bursitis are due to non-mechanical origins then success in restoring normal functions depends as much or more upon removing non-mechanical defects as in correcting of gross pathological and attitudinal abnormalities.* This idea is substantiated by repeated mechanical manipulations which have been tried to relieve conditions, that have increased irritations instead, and have resulted in prolonged convalescence in certain instances. The idea is borne out also by spontaneous subsidence of symptoms in many patients who have not received any purposeful surgical or orthopedic treatment. Fortunately pathological abnormalities often are corrected by physiological processes of repair in the tissues themselves; and also by normal healthy tendencies of individuals toward spontaneous restoration of favorable vascular states.

The great importance of skillful regulations of personal hygienic measures, therefore, should be realized by surgeons and orthopedists. And ways of modifying vascular conditions quickly and accurately should be used by them as well as by internists, although surgical interference may be the one

thing needed and lacking in occasional instances. It is possible to apply simple effective principles of treatment often, which have been established by prolonged complicated studies in internal medicine, chemistry, biology, and bacteriology; and without having to repeat or understand necessarily in each case the details of complicated special clinical and laboratory tests upon which such principles are based.

Diet, for example, is recognized by everyone to influence health profoundly; and quantities, qualities, and frequencies of taking of food and water are of great moment. It is possible to find right amounts, kinds, and times for individual cases, however, without knowledge of caloric requirements, or theories of digestive processes. Turning back once more to Codman's cases, among the thirteen of nontraumatic origin one was a large, vigorous looking, nervous, rheumatic physician of sixty-two years; another was a small, wiry, poorly developed woman of thirty-eight; a third was a debilitated, anemic, flabby old woman in a desperate condition of nervous exhaustion; a fourth was a tall, overgrown girl of fifteen years, with unusually loose, limber joints and in general good health; another was a thin, nervous, tobacco-soaked Italian cigar maker; another a well-developed, healthy-looking woman, and so on. Quantities of food best adapted to these various individuals' personal needs are variable amounts, and do not have to be determined according to their heat values, or grams per kilo of body weight. They can be estimated safely from observations upon the individual's stature and physical development, from changes in weight from time to time, from appearance and disappearance of digestive symptoms, and other simple observations. If the patient is large and heavy, has a vigorous appetite, and is putting on weight, it is proper to cut down the diet from the amount that is being taken. The right amount to be omitted soon can be found by a few repeated trials. If the person is small and thin with very good appetite, presumably the absorptive functions of the digestive tract, or the ability of the body tissues for taking up food from the blood is below normal, and diets therefore should not be lessened. Digestive organs and body tissues may be stimulated instead in rational ways and diets may be experimentally increased.

If there are good development and good weight, with failing appetite, and tired-out condition, then diets are diminished rather than increased, because with increases there will be mainly increase in intestinal bacterial fermentative and putrefactive processes. These are likely to produce further arthritic, rheumatic, and neuritic symptoms from mild autointoxications. When a patient's history reveals the fact that very large meals are eaten regularly, alternating with smaller ones, it is an easy matter to readjust them, substituting uniform and moderate ones in place of large ones. Or if there are gross irregularities in the intervals at which food is taken, these peculiarities need no special knowledge for their correction beyond knowledge of the mere fact of their existence. Likewise the advantages of very low diets occasionally for a day or so, alternating with moderate quantities can be learned only by trial and should be experimented with cautiously.

In determining appropriate combinations and qualities among articles of food it is possible to diminish slowly, and experimentally, amounts of meat, fish, eggs, and other nitrogenous sorts. Substitutions of carbohydrates for a part of the meat, with observations subsequently upon effects produced upon patients' general feelings and strengths and variations in weight, are easy to carry out and often are efficient in improving the individuals' conditions.

Symptoms arising from too large proportions of carbohydrates in the diets, shown by increase in gastric distress, fermentations, eructations, etc., are simple guides to further modifications until suitable proportions can be discovered. Much can be done without repeated analyses of gastric contents, or without other laboratory tests.

It is to be understood, however, that all careful tests and precise observations are of vital importance for progress in internal medicine, yet that they need not be employed always in every orthopedic case in order to restore health. And it seems better for orthopedists and surgeons to carry on effective medical measures simply and symptomatically rather than omit them entirely as the tendency is to do.

Regulation of eliminative functions of the intestines includes various methods of mechanically aiding peristalsis by exercise, increasing the volumes of intestinal contents by inert substances like agar, mechanically rinsing out the colon regularly and thus preventing harmful absorptions from it, and by pharmaceutical means producing a flow of fluids from body tissues into the lumen of the intestinal canal, or through direct irritative effects of drugs upon the mucosal walls of the intestine itself. All of these familiar purgative treatments will not be entered into in detail, but insistence that they shall be remembered is emphasized, and the fact again is pointed to that they are neglected frequently by surgeons and orthopedists in treating diseases of the extremities.

Regulations of kidney eliminations are perhaps as important as regulations of functions of the alimentary tract, but they cannot be fully discussed. Estimation of functional powers and ordinary activities of kidneys can be made roughly from the volume and specific gravity of the urine; and changes in amounts of water drank and food taken should be prescribed from these simple observations in addition to the diet indications revealed by gastroenteric symptoms and signs.

It is well for orthopedists and surgeons to remember that urine examinations for albumin and sugar help to show the existence, or absence, of renal disease; but that they do not measure renal capacities. Quantities of urea, uric acid, and indican in the urine are of more importance in furnishing data for regulating nitrogenous foods of the diet. Small quantities of waste products in the urine from tissue metabolism we are now learning may be associated with excessively large amounts of the same substances in circulation at times; and that these variations are due to kidney defects of which the ordinary urine analyses show nothing.

Comparisons of quantities of special excreted products with quantities of food taken are not accurate enough to show the slow accumulations and fluctuations taking place in the blood stream. Quantitative blood determinations alone satisfactorily settle this very important point, and these at present are clinical impossibilities except in a few very special instances. Knowledge of the possible existence of such abnormal vascular concentrations and how they develop, permits their recti-

fication, however, without direct proof of their existence sometimes, through watching changes in symptoms following appropriate changes in diet; inducing increased eliminations from the bowel, and from regulations in kidney functions. Variations in blood pressures modify renal functions and digestive capacities also to very important degrees; and because they do alter vascular proportions in this way from time to time, they ought to be always considered in shoulder cases.

When there are low blood pressures and anemias, as are so often seen in adolescence and in mild intestinal autointoxications, then strychnine or some other general stimulant combined with iron is especially indicated. Arsenic and quinine are other drugs that long use in the past has justified as general tonics in these conditions.

These are well-known facts that can be readily lost sight of in too exclusive interest in ether manipulations, operations, and the surgical healing of wounds; but medical procedures, let it be recalled, account for half the successes and failures.

The only causes imaginable for the drooping shoulders, relaxed muscles, and stretched ligaments associated with adolescence and mild autointoxications of adults, apart from effects of gravity, are peculiarities of the blood. These peculiarities show themselves in the same anemias mentioned as occuring in persons who are growing rapidly; and in sallow skins, low blood pressures and mild secondary anemias of intestinal toxemias.

Stoop shoulders require corrections of vascular defects, or there is spontaneous recovery in time without treatment, before normal conditions can be regained; and these circulatory defects deserve attention exactly as much as orthopedic supports and braces in the purposeful practice of medicine.

The only causes imaginable likewise for many instances of neuritis and muscular rheumatism are in peculiarities of the blood. Severe lesions of nerves are well known, and their causes are recognized to be due at times to vascular origins in alcoholic neuritis, lead palsy, and diabetic neuritis. But apart from these graver conditions, it seems that many shifting so-called rheumatic pains are simply responses of the nervous system—nerve cells or peripheral nerves—to slight irritations of an inferior quality of blood. It is known that slight rheumatic and neuralgic manifestations occur in debilitated and plethoric states similarly as gouty and arthritic symptoms do; but the chemical nature of the irritating substance, or substances, is unknown.

Perhaps the same constituents which produce irritations in synovial membranes and periarticular connective tissues also affect the nerves and muscles, or it may be proved sometime in the future that the latter symptoms are due to acidosis, or suboxidations, or some other special processes now unknown. Many physicians are sceptical about the existence of muscular rheumatisms and neuritis of obscure origin, and try to make definite pathological lesions to explain all of these cases. But it seems to the writer, while this effort at more definite diagnosis is a step in the right direction, that there is a possibility of assuming unwarranted precision, and of extending the importance of gross lesions beyond their real limits. There are chemical causes which are of equal or greater importance although they cannot be as easily demonstrated.

Practising physicians do not usually examine patients thoroughly for the tender spots that exist in muscles and along the course of nerves, and it is only in massage and osteopathic treatments that the frequency of these lesions is well appreciated. Physicians therefore generally are sceptical about these demonstrable effects of faulty blood conditions; and the writer has been very doubtful himself about such areas of tenderness until he has had them demonstrated in patients after having personally overlooked them.

Small localized tender lumps in the trapezius muscle that were resistant, as though they were due to muscle spasm, could be felt in individuals complaining of indefinite rheumatic shoulder pains. These could be softened by massage. Around the cervical vertebræ, at the level of some of the nerves which go to form the brachial plexus in other patients, there were localized spots upon which very slight pressures caused sharp shooting pains down the arm. Such patients say they are gradually relieved of their arm symptoms by massage, and by passive motions of the cervical vertebræ, with gentle rhythmical longitudinal stretchings and rotations of the neck.

It should be realized that presumably the spine is subject to lesions as well as all other living joints or bursæ; and when considering shoulder pains it is advisable to remember in some instances that causes of symptoms can be far back around the spine.

It is difficult to say what such mechanical stretchings and gentle manipulations of the neck do. They probably mean that the vertebræ are pulled apart just a little, with very slight sliding movements in the articular processes of the vertebræ. Perhaps there is, as a result, some slight influence upon intervertebral foramina which transmit nerves, arteries, and veins. It is conceivable that congestions and slight pressures at these narrow foramina may be altered and relieved sometimes; and certainly something must account for the shooting pains down the arms when the localized sensitive spots are touched.

These sharp pains are surely evidences that nerves are unusually sensitive, and it seems as justifiable to think abnormalities among the complex conditions about the vertebræ exist as causes of arm pains occasionally, as to believe that neuritis always comes from irritations lower down in the brachial plexus; or that stiff shoulders are caused only by bursal lesions. Masseurs and osteopathic physicians claim that these painful areas and lumps are very common, and that patients sometimes can be soon relieved from these relatively mild troubles by mechanical treatments.

Finally have to be mentioned physical therapeutic methods other than massage, that are used in treatments of shoulder conditions. Baths, electricity, hot and cold applications and bakings are the principal kinds, and it seems true that their efficiencies can be demonstrated here as for other localities of the body. There can be no doubt about the general stimulating effects of tonic baths; but frequently they are used in debilitated states when rest is indicated instead of stimulation; and they produce ill effects rather than good ones. But during stages of convalescence, and in some patients who have not already reached the limits of their vitality, they produce important beneficial influences and are very powerful general tonics in addition to the usual tonic drugs. Rheumatic and neuritic types of shoulder pains respond especially well to carefully regulated hydrotherapeutic measures; but ex-

pectation that acute inflammations or adhesions will promptly disappear under such treatment of course is unreasonable.

Local applications of heat and cold as wet packs are subject to same limitations as other physical measures. Baking is a benefit if it is not carried to the extremity of fatiguing the tissues, and it is more effective when the latter are recovering from their struggle with unfavorable conditions. High frequency electrical treatments will often stop instantaneously slight rheumatic and neuralgic sensations, and therefore ought to be classed among the useful physical therapeutic agents.

Summarizing the treatments for shoulder troubles, it may be said that medical features should be given attention in every instance. Sometimes physiological defects in blood and tissues correct themselves without supervision, but with medical care the course of the trouble should be shortened.

Supportive orthopedic measures should be considered also in every instance, for sometimes the changes taking place as a result of mechanical injuries, as well as irritations and pullings upon weakened tissues by movements and by weight of the arm, delay recovery.

Surgical interference is indicated as a general rule in subdeltoid bursal cases after six months, and ether manipulation earlier in adherent bursae. Some cases may continue for several years unless there is surgical interference, and this may be the one thing which is lacking in treatments of severe types.

Internal medical therapeutic measures in severe shoulder lesions, roughly speaking, are just as important as the more pretentious easily understood orthopedic, surgical, and physical therapeutic ones, and should be employed in addition to the others, even in traumatic cases.

Any of the chemical, physical, physiological, anatomical, surgical, mechanical, or pathological factors may be causes of delay in recovery; and therefore it is apparent all should be considered carefully in every case of painful or stiff shoulders.

In order to increase the total number of patients relieved there must be continual care observed to avoid losing, through diminished understanding of situations as a whole, all that is gained from increased efficiencies of special treatments. Increasing lack of general understanding is the natural accompaniment of extreme specialism; and this deficiency ought to be avoided, if progress is to be made, by frequent comprehensive short reviews of the principal ideas which are held and the usual methods of treatment that are in use, as has been attempted in this paper.

# METABOLISM AND VITALITY.*

By JOHN BENJAMIN NICHOLS, M.D.,

WASHINGTON, D. C.

It is the purpose of this paper to consider some pathologic, therapeutic, and hygienic aspects of the metabolic and heat-regulating processes of the body.

The subject may be introduced by a consideration of the question of vitiated air and ventilation. For a long time the view has been prevalent that the harmfulness of air contaminated by the accumulation of the gaseous products of respiration is due to a toxic action of such products. The substances responsible for the toxic effects have been supposed to be those of nitrogenous character and carbon dioxide. The latter especially, from the prominent part it plays in respiration and the facility of its estimation, is taken as an index if not the cause of the harmfulness of the air, and its amount forms the mathematical basis of schemes of ventilation. The amount of carbon dioxide in pure country air is about 3 parts in 10,000; air becomes perceptibly foul when this amount is more than doubled; and ventilation, it is held, should be so conducted as to keep the carbon-dioxide content of the air below 10 parts per 10,000.

The diminution of oxygen in breathed air is too small to produce any material ill effects, and may be dismissed from consideration as a cause of any trouble.

Experimental investigation has entirely failed to substantiate the toxicity theory of vitiated air. Aside from carbon dioxide, repeated attempts have completely failed to disclose the presence of any toxic principle in expired air. And with respect to carbon dioxide it has been found that many times the amount of this gas that is ordinarily regarded as unsafe can be present in the inspired air, under proper physical conditions, without causing any inconvenience or harm. Thus, in Benedict and Milner's experiments, subjects experienced no inconvenience from a prolonged stay (up to nine days) in the respiration chamber breathing air containing in 10,000 parts an average of 85 parts of carbon dioxide (28 times the normal), the maximum for three-hour periods being 231 parts (or 77 times the normal); these amounts were 9 to 23 times the maximum considered allowable in proper ventilation. Vitiated air has a characteristic foul odor; but it is evident that this odor is due to harmless substances, or to substances present in amounts far too small to produce any harmful effects.

Under these circumstances it seems obvious that

*Read before the Clinical Society of the District of Columbia, October 13, 1913.

the current views as to the cause of the harmfulness of contaminated air must undergo revision. Of the harmfulness of such air there can be no question; it is attested as well by everyday experience as by such tragic examples as the Black Hole of Calcutta. If this noxiousness is not of toxic origin, what is its cause? The indications are that it is due, not to chemical, but to physical causes, namely, interference with the escape of heat from the body.

If the heat generated by body oxidation had no means of dissipation it would be retained and the temperature of the body would quickly rise to a point incompatible with life. Fifty-eight calories are sufficient to raise the temperature of a medium-sized individual 1° C. (1.8° F.). Were there no heat loss, the body temperature of such a person would in three hours' time rise to 43° C. (109° F.). The imperative necessity to life, health, and comfort of constant and adequate escape of heat from the body can be realized from these considerations.

There are two main avenues of discharge of heat from the body: by conduction and radiation, and by vaporization of water.

When the temperature of the surrounding atmosphere is less than that of the body, heat is given off from the latter by radiation and conduction. The greater the difference of temperature the more rapid and vigorous is the escape of heat. Motion of the air facilitates the convection away of heat, and cold baths effect an active abstraction of it.

The large amount of water given off in the form of vapor in the perspiration and expired air also carries away a large amount of heat, as the vaporization of water involves the absorption of considerable heat in latent form. Each gram of water converted into vapor represents the absorption of 0.592 calory of heat. It should be noted that the sensible perspiration does not carry away heat in this way, but only the aqueous vapor. Loss of body heat by this channel is promoted by conditions which favor vaporization of water, such as a low degree of humidity of the atmosphere, an elevated temperature, and motion of the air.

Certain conditions of the atmosphere may hinder or even entirely prevent the escape of heat from the body. When the temperature of the air becomes the same as that of the body there can be no discharge of heat by radiation-conduction; and when the atmosphere is saturated with watery vapor the vaporization of more water is prevented or greatly interfered with. Hence, increase of the temperature and increase of the humidity of the atmosphere both interfere with dissipation of body heat. When either condition exists alone, the margin afforded by the other may suffice amply for heat escape and body comfort. Thus, dry air at high temperature, or damp air at low temperature, allow for proper dissipation of heat. When, however, atmospheric heat and humidity exist together, all the avenues of heat loss are blocked and heat must necessarily accumulate in the body, with resulting discomfort, harm, and danger. It is these factors that cause the discomfort of hot weather and produce such pathological conditions as sunstroke.

Whenever the presence of people in a confined space causes contamination of the inclosed air by waste respiratory products, the temperature and humidity of the air are both likewise increased; and as shown by a number of investigators, it is apparently the interference with the elimination of body heat so brought about that is responsible for the ill effects of vitiated air, rather than any toxic action of the waste products. In the experiments of Benedict and Milner, cited above, the temperature of the air was maintained at 20° C. (68° F.) and the humidity averaged 67 per cent.; under these conditions, allowing for ample heat discharge from the body, an enormous increase of carbon dioxide in the inspired air caused no inconvenience or discomfort whatever. The primary essential in ventilation is therefore the control and reduction of the temperature and humidity of the air.

Many examples are afforded in the treatment of disease conditions in which the promotion of the elimination of body heat is a prominent factor, although we perhaps do not appreciate this action so distinctly as we might. Cold bathing in fever is a powerful means of abstracting heat from the fevered organism. The favorable results of removal of patients and invalids from cities in the heated term into the country or climatic resorts are probably mainly due to improvement in the conditions for heat elimination brought about by the lesser heat and humidity of the latter. The fresh-air treatment of tuberculosis and other conditions probably owes its efficacy to similar causes. The motion of open air greatly increases the abstraction of body heat, both by radiation-conduction and by evaporation; and this is an important factor in outdoor treatment. All the attempts at explanation of the benefits of the fresh-air treatment on chemical grounds have been unsatisfactory and inconclusive; the differences in content of oxygen, carbon dioxide, impurities, etc., do not suffice to explain the differences in therapeutic action. The physical differences affecting heat elimination afford a much more plausible explanation.

The pathological conditions induced by insufficient heat elimination would *per se* form an important subject for consideration that has not yet been adequately elucidated. The promotion of heat elimination does not, however, merely avert these conditions, but has an additional profound effect on metabolism that doubtless yields further beneficial results. The abstraction of heat necessitates oxidation to replace the heat so lost. Conditions and procedures that promote heat-discharge increase and stimulate body oxidation and metabolism. This has been abundantly shown by experimental research, and is attested by the familiar experience of the heightened appetite produced by exposure to cold, wind, and cool bathing.

In the strictest sense, oxidation is life. All vital energy and activity come from the combustion of organic material. That flame is the flame of life. The more material we oxidize the greater is our activity and vitality, the more we live. It would therefore appear that the stimulation of oxidation or metabolism has an energizing influence on the organism, and is important to the conservation of health and the cure of disease.

In general, body oxidation may be stimulated in either an active or a passive way. Muscular action has by far the greatest share in producing body oxidation, and the beneficial effects of exercise are probably largely due to the stimulation of metabolism thereby effected. Voluntary muscular activity is not, however, available in the case of ill patients; and under these circumstances other means (passive) are necessary to promote metabolism. Means available to this end are such as increase abstraction of body heat, with a resulting

increase of oxidation to replace the heat thus lost; a considerable influence on metabolism can be thus exerted. It is a reasonable supposition that the value of the open-air treatment, of exposure to cool, dry, moving air, of cool baths, etc., results both from the primary increase of heat discharge and from the secondary stimulation of metabolism thereby effected.

The debilitating effects of inactive, sedentary, indoor life are a familiar exemplification of the consequences of a low regimen of oxidation and heat elimination. Vigor and health are associated with active metabolism and free heat dissipation. The breezes that play about us literally fan the flame of life; stuffy rooms stifle that flame. The factors that vitalize the well ought also to operate to energize the ill.

These considerations may have some bearings on certain mooted questions as to dietetic standards. There are numerous adherents to the doctrine that dietetic standards should be reduced to the lowest point compatible with the maintenance of efficiency. It is, however, by no means "self-evident," as they put it, that the lowering of metabolism to the minimum is productive of the greatest benefit to the organism. On the contrary, there is ground for the belief that the greatest benefit comes from a reasonable augmentation of metabolism. It may be possible to exist on an energy equivalent of 1,500 calories a day; but the individual who lives on a scale of 3,000 calories, doubling the oxidation, gets twice as much action and vitality out of life. These considerations in my judgment warrant generous dietetic and caloric standards.

The necessity for ample heat elimination is especially urgent during muscular activity, as a large excess of heat must at such times be discharged. The discomfort of labor in hot and humid weather or situations exemplifies this. Exertion should therefore be minimized under such circumstances, and workmen necessarily exposed to heat or confined in close quarters, as furnacemen, stokers, etc., should be afforded free draft of air and every other available means for removing body heat. Living rooms in winter are usually overheated, and this condition should engage physicians' attention and advice more than it now does.

Climatic conditions suitable for therapeutic purposes are in many cases impossible of attainment on account of prohibitive expense or non-transportability of very ill patients. Meteorologic conditions at best are fortuitous and uncertain. If atmospheric and other conditions influencing the elimination of heat could be artificially regulated and controlled, at a practicable cost, our therapeutic resources would be immensely augmented. There would be four factors involved in such control, namely, clothing, motion of the air, temperature of the air, and humidity of the air.

Clothing is entirely under control. Reduction of clothing facilitates the escape of heat from the body by both radiation and evaporation, and some beneficial effect is obtainable in this way.

Motion of the air can also to a large extent be obtained and maintained at will, as by means of fans if natural breezes or means of ventilation fail. Air movement is an important adjuvant to the removal of heat by both conduction and vaporization, and is alone in many cases sufficient to afford needed relief.

The control of atmospheric temperature is practised on a large scale in the warming of our houses and buildings in cold weather. The opposite procedure, the artificial cooling of air or rooms, is successfully and extensively employed, at some expense, in refrigeration plants, and has been practised to a very limited extent in hotels, ships, and hospitals. This is accomplished by the use of cold currents in coils in the rooms or in the entering air supply.

Control of atmospheric humidity is practicable to a certain extent. The relative humidity of air varies with its temperature, without any change in the absolute amount of watery vapor present; the same air which at a high temperature is relatively dry, when cooled to its dew point becomes saturated with moisture. The factor of physiological importance, such as the effect on the respiratory mucous membranes, or on heat elimination, is the relative humidity of the air and not its absolute water content. The moisture of the air can be easily increased by providing for the evaporation of water placed in open receptacles in warm situations. The opposite procedure, the removal of moisture from the atmosphere, is a more difficult and expensive matter. It can be accomplished in connection with a refrigerating system by cooling the air current to a temperature below that at which it is to be delivered into the rooms, and condensing out the surplus moisture at that minimum temperature; the subsequent partial warming of the air gives it a humidity less than saturation.

An expedient for cooling rooms that can be easily extemporized wherever electricity is available has been devised by Dr. W. J. Manning of this city. (*Journal of the American Medical Association*, June 4, 1910, LIV, 1848.) This consists in directing a current of air from an electric fan against a suspended cloth kept saturated with water; the evaporation of water brought about in this way effects a considerable lowering of the temperature of the room.

Another cooling arrangement, a cool bed for infants, has been devised by Dr. Alfred F. Hess of New York (*Archives of Pediatrics*, May, 1912). This consists of a bed partially surrounded by a tank of ice and ice water, which effects a lowering of temperature of 7° to 10°.

The employment in hot weather of rooms in hospitals with artificially cooled and dried air supply, which could probably be effected at a cost not prohibitive, ought to be of great benefit in many cases of disease. Such refrigerated rooms or wards would doubtless be of service in the treatment of fever cases; and it is possible that benefit not anticipated might be realized by treating such cases at low temperatures, lower than have yet been available. The atmospheric conditions would be under control, and those yielding the best results could be maintained. The method also seems highly promising for the treatment of sick children in hot weather; the beneficial results of removal of such patients to cool country resorts are well known, and it is probable that equally good or even better results would be obtainable in cooled rooms in city hospitals. If refrigerated wards were available in cities in the heated season, critical cases could be at once placed in them, and it is likely that many lives could be saved in that way. The method has been employed only to a very limited extent in hospital practice, as in the Boston Floating Hospital for Children, where the results are said to have been excellent; and it would seem to be a most promising one for investigation and general introduction.

# BACTERIEMIA, INFECTIONS, AND BRIGHT'S DISEASE.

By W. C. K. BERLIN, M.D.,

DENVER, COLORADO.

Dr. Richard Bright in 1827 described a form of kidney disease characterized by the presence of albumin in the urine. Since that time much knowledge has accumulated, and with this knowledge many classifications have been made according to symptomatology and findings, such as acute and chronic nephritis, chronic interstitial, parenchymatous, etc., together with many subdivisions, according to the different symptoms and débris found. The so-called degenerations are also classified according to symptoms and findings, such as amyloid, wax, etc.

Heretofore no good opinion has been expressed as to the cause of nephritis, most authors and students along these lines have expressed an opinion that the cause was degenerative, nutritive, nervous, cardiac, vascular, etc. More recently intoxications, and toxemias, from different causes, have been advanced as the cause of nephritis.

By gaining exact knowledge of the pathology of such conditions bacteriology has cleared up many obscure diseases. Many diseases have been robbed of their mystery by the use of culture media and microscopes, and many more are on the verge of losing their mysteries. Recent investigations carried on in blood cultural work has proved the presence of bacteriemias of different characters, and along the same line of investigations it is shown in what manner these bacteriemias may occur.

The convincing work of Adami on intestinal stasis, bacteriemias, and sub- or latent infections has shown the celerity with which the colon bacillus and other bacteria can pass through the intestinal wall, under certain conditions; for instance, simple distention of the gut causing a mechanical paralysis or stasis, thereby allowing the migration of the colon bacillus and other bacteria into the surrounding tissue, and finally into the circulating blood, there to produce an active bacteriemia, or not, depending on the resistance or immunity of the subject.

In the light of recent work done by myself one must always conclude that an infection preceded by a bacteriemia is the essence of these different conditions, known under the general term of Bright's disease, or nephritis, except possibly the true degenerations, and these also may be traced back to an original infection.

Acute nephritis, such as follows frequently the acute infectious diseases, differs little from the so-called Bright's disease. In acute nephritis there appears more débris in the urine, in the form of a greater variety of casts in addition to the blood, pus, and kidney cells. As this condition becomes subacute the excessive débris decreases, and as the conditions becomes chronic this débris almost entirely disappears, leaving albumin and casts as factors in classifying the different forms of the degenerative types of the conditions known as Bright's disease.

In a recent issue of the *Journal of the American Medical Association* a symposium on Bright's disease by prominent men was printed, but the subject of infection as a causative factor in the development of the affection was not mentioned. Nearly all the writers were agreed that some form of toxemia was the cause of this ailment. Many thought it was an autointoxication or fermentation, or some other form of intestinal toxemia.

In accordance with investigations covering a period of four years the writer is convinced that most, if not all, the forms of nephritis known as Bright's disease, are preceded by a true infection, and may occur as sharply acute, mild, or of an insidious beginning. The latter may produce no marked symptoms and may only be found to be present accidentally, as in the examination of life insurance or other routine examinations.

Intestinal fermentation and intoxication seem to be responsible for blood-pressure changes only, and this condition is not associated with kidney disturbances of this character, except mechanically, as in other organs. Confirming this, we see many cases of high blood pressure unassociated with kidney complications of any kind; conversely, cases observed (one in particular) had an albuminuria of long standing with the sphygmomanometer registering a subnormal pressure.

These facts would lead one to believe that fermentations, intoxications, or toxemias are not associated with the acute or chronic forms of nephritis, but instead are responsible for high blood pressure conditions only. It is true one may find both infection and intoxication present in an attack of nephritis with high blood pressure, but the infection is the cause of the nephritis and the intoxication of the high blood pressure. Intestinal fermentation may be responsible mechanically, in the beginning, for a later infection of the kidney by causing a distention and intestinal stasis, allowing the migration of bacteria. This same fermentation with distention and stasis may cause a toxemia later with blood pressure changes. The distinction drawn from the foregoing facts is that all forms of nephritis are originally infectious and all true blood pressure changes are from toxemias.

The only true elimination of the waste matter of the blood stream occurs in the kidney cells, and these organs are so constructed that in their function there is present more likelihood of infection at this point than at any other during a blood stream infection.

In a former article entitled "The Sequelæ of Scarlet Fever," printed in the *Denver Medical Times* of July, 1909, attention was called to the infectious character of acute nephritis, often following scarlet fever. This complication has been prevented since that time by applying prophylactic treatment, directed in accordance with the findings in such cases. Not only is the intestinal tract responsible for these original attacks of nephritis, but other infectious diseases, such as tonsillar, pharyngeal, laryngeal, and other ulcers, also abscesses, many of which, or possibly all of this class, are of streptococcic origin. The pneumococcus and allied bacteria are often responsible. The staphylococci are not found to play any great part in bacteriemias or this class of infections, as they are usually confined to infections of the outer surfaces of the body.

A few case histories, briefly described, will apply to confirm the contentions made here that all cases of acute, chronic, and degenerative forms of renal disease are originally infectious diseases.

Case I.—P. H. Age nine years. Following an attack of ulcerated throat (not unlikely of scarlatinal origin), had an acute intestinal fermentation with distention producing a mechanical paralysis or stasis of the bowels, followed by complete suppression of urine and acute nephritis, with a most severe edema of all the tissues of the body. Acting as con-

sultant at this time, treatment was advised directed solely toward the intestinal complication, after the urine showed the infectious character of nephritis. This patient had an immediate, uneventful recovery.

Case II.—D. G. Age 11 years. Sister of P. H. Contracted scarletina two years later from an infected milk supply. This was also a veiled type, except for the ulcerated throat. Diagnosis was arrived at through the source of infection. Shortly after the diagnosis was made a mild or beginning nephritis was noted. Treatment directed toward the intestinal complication was sufficient to promote prompt recovery.

Case III.—Dr. B. Age 40 years. Had severe lordosis (hunch back) was treated for varying tubercular troubles for the last two years. Examinations and tests were negative to tuberculosis. Blood culture showed colon bacillus free in the circulating blood (a bacteriemia). Serial Roentgen ray examinations showed many changes in the intestinal tract indicating the source of the bacteriemia. Albumin and colon bacillus found in the urine. This patient later consulted a Cleveland, Ohio, surgeon for operative interference, but was told to go home, as he was about to die from tuberculosis. He died later from meningeal irritation or uremia, which caused many and severe convulsions. The cause was no doubt due to meningeal infection, or a severe type of nephritis by the colon bacillus.

Case IV.—R. M. Age 17 years. Elicited history of throat ulcer. He was treated successively after that for typhoid fever, spotted fever and tuberculosis. Examination eliminated tuberculosis. The sputum was positive to a streptococcus only, as was the urine also. Blood culture was negative, but this was a late case and the infection became localized, as was determined by the occurrence of a large empyematous sack in the pleura, which was drained. The urine contained all kinds of renal débris, *i. e.* kidney, blood, pus, and round epithelial cells. Casts were present in a great variety. Albumin registered five per cent. The draining of the pus sack and caring for the digestive disturbances was sufficient to promote rapid recovery.

Case V.—J. H. H., Jr. Age 16 years. Patient was of fine physique and excellent family history. Personal history of beginning of illness obscure. Three years ago, after an evening spent in the gymnasium in rather violent exercises, he was seized with a severe pain over right kidney (probably due to blood clot), followed by a hematuria, lasting about three weeks. During the past three years several attacks of severe hematuria have occurred, each attack apparently growing more severe in character and duration. After each attack there was present quite a severe anemia, but this condition improved before the next attack. The attacks were brought on, for the most part, by exposures to sudden temperature changes. Up to this time the urine had not been examined between attacks, or during any time after cessation of the hematuria. The patient came under observation during the last attack of hematuria. A systematic plan of examinations was instituted, as it seemed necessary to arrive at a diagnosis through a process of elimination. Physical examination revealed a beginning heart lesion, *i. e.* a noncompensating heart with a mitral regurgitation (probably an endocarditis from a former bacteriemia). Catheterized urine was heavily loaded with blood and gave a mixed growth on culture of the colon bacillus and staphlococcus. An *x*-ray was made which eliminated the possibility of a kidney stone or large tumor. Cystocopic examination revealed no cystic lesion. Catheterization of the ureters revealed both kidneys bleeding; this also eliminated a possible renal verax. On culture the segregated urine grew pure colonies of the colon bacillus, thereby arriving at a diagnosis of a subacute nephritis, with acute exacerbations of a purely infectious character. Treatment administered in accordance with the diagnosis controlled the bleeding. After the urine was clear the percentage of albumin was found to be 40. The specimen contained much débris, such as casts and cells of various kinds. Treatment directed toward the infection and also the evident intestinal complication brought the percentage of albumin down to 8 when last seen. About this time a temporary impairment of the circulation appeared in the form of a mild anasarca. Consultation was asked for at this time and granted. The consultant gave a bad prognosis and upon the advice of others (not professional) the parents took the young man to Excelsior Springs, Missouri. At this place a specialist was consulted, and, after a thorough examination(?), pronounced the ailment to be a "pure case of Bright's disease." The unfortunate part of this case is that the specialist, ignoring the case history and findings, is still treating this fine young man for Bright's disease and the patient is still suffering relapses, after being sent home each time as cured. It is the opinion of thinking professional men that the excessive water drinking at the average watering places only tends to overload the defective kidneys and make their burden the harder to bear.

The original work done and the actual cases cited above are sufficient to give birth to the opinion that the foregoing observations and deductions are based on, at least, circumstantial evidence.

*Conclusions.*—The transition of an acute nephritis to a chronic form is simply a clearing up of an inflammatory process, leaving an injured kidney with a beginning degeneration or Bright's disease.

If the urine was segregated in every case of Bright's disease and placed on culture media one might expect to find colonies of the different pathogenic bacteria.

The origin of Bright's disease is a true infection.

The toxemias are not the cause of Bright's disease.

Toxemias or autointoxications are responsible for blood pressure changes only.

More work is necessary along these lines by the profession to prove the above contentions, so that treatment can be administered accordingly, and which, of necessity, would vary greatly from the set treatment now in vogue for Bright's disease, as it is now understood.

202 Symes Building.

## FURTHER OBSERVATIONS ON THE USE OF THE HIGH FREQUENCY SPARK FOR THE RELIEF OF PROSTATIC OBSTRUCTION IN SELECTED CASES.*

By HENRY G. BUGBEE, M.D.,

NEW YORK.

CYSTOSCOPIST TO ST. LUKE'S AND WOMAN'S HOSPITALS.

In the August number of the *New York State Medical Journal*, I gave the report of fourteen cases of vesical obstruction, where relief was obtained from the destruction of tissue by direct applications of the high frequency spark. These cases included obstructions from a hard fibrous prostatic ring; prostatic nodules left after perineal operations; median bar obstructions; a small median lobe, and diffuse carcinoma of the prostate and vesical wall.

To this list of cases I can add four more cases of benign obstruction, and the same number of malignant cases, all treated in the same manner. I shall to-night report only the benign obstructions, as four of the eight cases of carcinoma are still under treatment and I wish to make further observations, before drawing conclusions.

I can say, however, that in all of the cases of malignancy the disease has been advanced, has been inoperable, and the patients have beeen greatly benefited, the vesical orifice freed, pain relieved, absorption lessened, and life made more endurable.

The cases of benign prostatic obstruction which are suitable for this method of treatment are as follows:

1. Small fibrous prostates, which form a hard ring about the vesical neck, not only constricting the internal urethral orifice, but interfering with the function of the internal vesical sphincter muscle.

*Read before the Genitourinary Section of the New York Academy of Medicine, Oct. 15, 1913.

| Patient | Age | Chief Complaint | General Physical Examination | Rectal Examination | Frequency | Stream | Type of Obstruction | Residual Ozs | Bladder |
|---|---|---|---|---|---|---|---|---|---|
| 1. J.M. | 41 | Hesitancy. Frequency. Burning urination. Loss of sexual power. | Negative. | Prostrate slightly enlarged throughout. Smooth. Firm. | Diurnal q 2h Nocturnal q 2h. | Poor force. | Median, posterior. | 3 | Normal. |
| 2. F.A. | 60 | Frequency. Burning. Inability to void. Persistent suprapubic fistula. | Suprapubic fistula following cystotomy for vesical calculus. | Moderate enlargement of prostrate. Firm. Smooth. | Diurnal q 1h. Nocturnal leaks from suprapubic fistula. | Urine comes in drops. | Collar of prostate from which project numerous small lobes. | 2 | Contracted cystitis. Trabeculations Marked. Many diverticula. |
| 3. V.A. | 67 | Difficulty in starting the stream. | Negative. | No enlargement of prostate. | Diurnal q 3h. Nocturnal q 4h. | Poor force. | Median, posterior. | 10 | Beginning trabeculation. No cystitis. |
| 4. J.C. | 66 | Difficulty in starting the stream. Frequency. | Diabetes. Urine contains 4% sugar. | Large lateral prostatic lobes. Smooth. Firm. | Diurnal q 1h. Nocturnal 8 times. | Poor force. | Median, posterior and lateral lobes. | 6 | Well marked trabeculation. No cystitis. Many diverticula. |
| 5. E.T. | 74 | Frequency. Dribbling. | Negative. | Moderate general enlargement of prostate. Smooth. Firm. | Diurnal q 1½ hrs. Nocturnal three times. | Intermittent. Poor force. | Median posterior with nodules of prostate surrounding the vesical neck. | 3 | Well marked trabeculation. Slight cystitis. |
| 6. J.M | 66 | Difficulty in starting stream. Retention one month ago (January 15, 1913.) | Dementia. Physical condition good. | Moderate general enlargement of prostate. Smooth. Firm. | q 1h. nocturnal and diurnal. | Dribbles. | Posterior elevation or bar. | 2 | Slight trabeculation. |
| 7. J.H. | 45 | Difficulty in voiding. Burning Frequency. Under treatment for 8 years. | Negative. | Prostate not enlarged. Smooth. Hard. | q 2h. nocturnal and diurnal. | Fair. | Posterior elevation or bar. | 2 | Normal. |
| 8. J.W. | 66 | Difficulty in voiding. Burning. Frequency. | Scar from perineal operation. | Lateral lobes of prostate removed by perineal route. | q 2h. nocturnal and diurnal. | Poor force. Dribbles. | Collar of prostatic nodules surrounding the vesical neck. | 10 | Marked cystitis. Trabeculation. Diverticula. |
| 9. B.K. | 65 | Frequency. Partial incontinence. | Negative. | Prostate not enlarged. | Diurnal q 1h. Nocturnal 3 times. | Poor force. Dribbles. | Collar of hard fibrous prostatic tissue about the vesical neck. | None | Moderate trabeculation. Slit in prostatic collar from perineal incision. |
| 10. F.D. | 74 | Complete retention. | Negative. Scar from perineal operation. | Lateral lobes removed. No lobes felt. | Retention. | Uses catheter. | Collar of prostatic nodules about vesical neck. | 16 | Marked trabeculation. Many diverticula. Atony. |
| 11. E.H. | 68 | Complete retention. | Negative. Scar from perineal operation. | Lateral lobes removed. No prostate felt. | Retention. | Uses catheter. | Collar of prostatic nodules about vesical neck. | 20 | Marked trabeculation. Many diverticula. Atony. |
| 12. S.P. | 57 | Frequency. Difficulty in voiding. | Negative. | General enlargement. Smooth. Firm. | q 2h. nocturnal and diurnal. | Poor force. | Median, posterior. | 4 | Normal. |
| 13. J.B. | 56 | Frequency. Burning. | Negative. Scar from former operation. | No prostate felt. Lateral lobes removed. | Diurnal and nocturnal q 1h. | Poor force. | Collar of prostatic nodules about vesical neck. Slight notch posteriorly. | 6 | Slight trabeculation. |
| 14. W.S. | 67 | Complete retention. | Uraemia following hernia operation. | Entire prostate enlarged and hard. | Retention. | Catheter. | General marked enlargement. | 40 | Marked trabeculation. Diverticula. Cystitis. |

2. Elevations of the median portion of the gland in the form of a bar, an elevation of the trigone, or more or less distinct median lobe, without general enlargement of the prostate.

3. Irregular prostatic lobes, narrowing the vesical outlet, or nodules of prostate left after incomplete prostatectomy.

4. Enlargement of the prostate of whatever size and form, where open operation is refused or contraindicated by the condition of the patient.

The method consists in the destruction of prostatic tissue, by direct contact with the high frequency spark, the current being applied by means of an insulated wire (usually No. 5, steel) introduced into the bladder through the cystoscope, in the same manner as originally employed by Beer, in the destruction of vesical papillomata.

Previous to the introduction of the cystoscope, the mucous membrane of the bladder and urethra is rendered anesthetic by the instillation of a solution of 4 per cent. novocain, in 1 to 16,000 adrenalin, which is allowed to remain in the bladder for one-half hour.

The cystoscope that I have found most satisfactory for this work is the No. 18 F. indirect, close vision instrument, made by Wappler, and called by him "The 1911 Model." This cystoscope is of a comfortable size, gives a good field, is easy to manipulate, and renders work at close range possible, so that it can be used in the urethra as well as about the vesical neck. The irrigating cocks are convenient. I have had no trouble with short circuiting, even with the high frequency and cystoscopic currents both turned on.

The wire introduced through this instrument, is by means of the deflector, held tightly against the tissue to be destroyed, and the current turned on. The strength of current varies with the amount of tissue to be destroyed. As a rule a 1-10 inch spark in the muffler is sufficient, and the spark should be tested before using the current in the bladder. The wire is usually allowed to lie in position until the bubbles cease to form. This usually requires about one minute, and is a long enough application for one area. The destruction of tissue for this length of time, with the current stated, extends about ¼ inch below the surface.

As many applications should be made as the patient can take, without causing severe pain or too deep destruction of tissue. The application of the

| Oct. 20, '12 | 2 | 8 | Nov. 8,'12 | Moderate amt. of pain. | None. | Sep. 29, '13 | Normal function. Empties bladder. No return of nodules about vesical neck. |
| Apr. 15, '13 | 3 | 9 | May 21,'13 | None. | None. | Oct. 1, '13 | Better stream. No residual. No incontinence. Wide furrow through posterior aspect of prostatic cellar. |
| Mar. 2, '13 | 3 | 9 | May 21,'13 | None. | None. | Sep. 15, '13 | Reports using the catheter once a day only. Residual 8 ounces. No discomfort. Voids freely. |
| June 12, '13 | 1 | 4 | ..... | None. | None. | Sep. 26, '13 | Uses catheter once a day. Voids freely. Residual 6 ounces. No return of posterior obstruction nodules. |
| Nov. 20, '13 | 4 | 10 | Sep. 19, '13 | None. | None. | Sep. 29, '13 | Voids freely. 1 ounce residual. High frequency applied to median obstruction. Narrow furrow through median bar. |
| Sep. 13, '13 | 3 | 9 | Sep. 26, '13 | Pain and burning after third treatment. | None. | Sep. 30, '13 | Voids better. Residual 2 ounces. Less frequency. Posterior nodule one-half destroyed. |
| July 2, '13 | 3 | 9 | Aug. 6, '13 | Temperature after each treatment. | None. | Sep. 29, '13 | Patient voids. Residual 6 oz. Bladder in fairly healthy condition. Very little discomfort. Deep furrow through median obstruction. |

spark causes the feeling of being pricked with needles. Pain is often absent and seldom acute, and disappears as soon as the current is turned off. With the application of the current, the insulation burns off the wire, necessitating the withdrawal of the wire after each application, cutting it off flush with the insulation and reintroducing. The field fills with bubbles, requiring the injection of an ounce or more of fluid through the side cock, which clears the field at once. Bleeding is almost never seen, if manipulations are carefully executed.

It is better to have several sessions, even eight or ten, destroying a little tissue each time, giving the patient very little pain, no after irritation, no bleeding, and not incapacitating him, rather than to make each treatment too extensive, thus giving rise to the above disagreeable features.

Immediately following the application, if the wire is withdrawn, one sees a distinct excavation, with ragged, grayish walls. This gray tissue comes away in small shreds and flakes, a little at a time, and does not leave an ulcerated surface. When the dead tissue has entirely passed off, an apparently smooth, healthy surface is seen; a depression in place of the former elevation. I have seen no infection in these areas. It requires about ten days for all the tissue from a single burning to come away. The treatments should be repeated until the obstructing tissue has been destroyed, the intervals varying in each individual case. It has not been necessary in any of the cases to confine the patients to bed after the applications, but occasional bladder irrigations are desirable.

This method, it seems to me, has every advantage over the operations, such as: open incision and stretching of the vesical neck; the cautery operations of Bottini, Goldschmidt, and Chetwood, and the intraurethral punch operation of Young.

The advantages are, that the cause of the obstruction is removed, under the eye, without pain, reaction, infection, loss of function, hemorrhage, or incapacitating the patient. There is no ulcerated surface left, hence no cause for cicatrization.

The cases given in this chart are:—

1. Small fibrous prostate, constricting the vesical orifice. One case: The patient had been operated by perineal incision and stretching of the vesical neck, with very little relief and partial incontinence since the operation. This patient has been greatly relieved, since the partial destruction of the

prostatic collar, in the ease of voiding, loss of frequency, and better control.

2. Median prostatic elevations or prostatic bars. Two cases: The symptoms have been relieved and both patients empty the bladder.

3. Small median lobe, without general prostatic enlargement. Three cases: Relief of symptoms. No residual.

4. Moderate general adenoma. One case: This was a suitable case for prostatectomy, which the patient refused. The symptoms have been diminished and the residual eliminated.

5. Moderate general adenoma. One case: This patient had diabetes and was not considered a good operative risk. This patient's symptoms have disappeared. He has no residual.

6. Very large general adenoma. One case: The patient has a severe grade of nephritis, and was not a justifiable risk for radical operation. He has been greatly relieved by the applications of the high frequency spark, and is still under treatment.

7. Collar of prostatic nodules, surrounding the vesical orifice, causing obstruction. Four cases: In all of these cases the lateral lobes had been removed through the perineum, without relief of symptoms. One of these patients was subsequently operated by the intraurethral punch method of Young, following which the amount of the residual increased from four to six ounces, and none of the symptoms were relieved. With three treatments with the high frequency spark, the residual has been reduced to two ounces and now to one ounce, the patient has no frequency, and a good stream. Two of these patients had atonic bladders, with many large diverticula. The residual in these cases has been reduced in amount, and the necessity of catheterization made less frequent. In the fourth case the residual has been eliminated.

8. One more case of irregular prostatic outgrowths has been entirely relieved.

*Summary.*—1. The cases of small, fibrous prostates, median bar elevations, and small lobe obstructions, without general enlargements, have been symptomatically cured.

2. The cases of obstruction from a collar of prostatic nodules, without lateral lobes, have been completely relieved where the tone of the bladder was fair, and improved even where the bladder wall was atonic.

3. Cases of general adenoma, where open operation was contraindicated, were greatly improved.

40 East Forty-first Street.

## THE UPPER RESPIRATORY MUCOUS MEMBRANES AS EMUNCTORIES.

By J. A. HAGEMANN, M.D.,

PITTSBURGH.

When one contemplates the remarkable success that has of late years attended the researches into biochemistry and into the functions of the cell in assimilation, secretion and excretion, and how efficiently this knowledge has been applied in the treatment of metabolic disturbances in various portions of the body, it is astonishing that we are so tardy about adapting this knowledge to some of the common pathological conditions met with in the upper respiratory regions. Textbooks as well as treatises in journals continue to devote much space to descriptions of polysyllabic-named bacteria that are found in the mucus taken from a moist nostril. Truly, we have become "bug-mad." Like the mythological Wodan, who sacrificed one eye that he might see the better with the other, we are become monocular in our perpetual search for the germ that "walketh about, seeking whom he may devour."

Ignoring for the nonce the enemies that assail our gateways from without, let us scrutinize some of the influences from within that induce a pernicious effect upon the upper respiratory passages. Primarily there come to our mind the severe irritations of nose, throat and mouth which are encountered during the course of the exanthematous diseases. In measles an acute rhinitis is recognized as one of the incursive symptoms. Koplik's spots in the mouth are pathognomonic. In scarlet fever the exanthem extends to the nose and throat, and sometimes there is a diphtheroid condition of these organs during the disease. In roetheln, as Forchheimer first indicated, one sometimes meets with a delicate, small-spotted, rose-colored exanthem on the soft-palate and pharynx previous to the appearance of the eruption on the skin. The severe inroads which scurvy makes on the buccal mucous membrane precede any other manifestation except the characteristic languor. Diphtheria locates its detestable pseudo membrane in the throat and nose. During the course of acute leucemia notable forms of stomatitis are observed, sometimes progressing to necrosis. These instances, known to every practitioner, are merely cited to show that certain specific poisons, whose precise nature need not concern us in this discussion, evince a predilection to display their primary eruption through the upper respiratory mucous membranes.

Apparently, according to our present state of knowledge, it may be assumed that epithelium exercises a selective action upon substances which are conveyed by the blood-current. When a cell takes up from the blood-current any material, that material becomes an element in the metabolism of such cell. Certain substances which circulate in the blood produce a markedly irritating effect on the cells whose function it is to excrete these respective substances. The bowels, kidneys, skin and lungs chiefly are engaged in disposing of the waste products of metabolism. Sometimes, however, for obscure reasons, one or several of these emunctories become unable to cope with the poisonous excreta, and the function must be performed vicariously. A sudden chilling of the cutaneous surface may suppress transpiration and thereby precipitate a severe coryza. When so patent an etiology does not exist, one might assume that for biochemical reasons the skin and other excretory organs were incompetent to expel certain materials, and these, circulating through the arterioles of the upper respiratory mucous membranes, might thus find more adaptable affinities in the group of epithelial cells there located.

The behavior of some nasal mucous membranes after ingestion of the iodides is universally recognized. The administration of infusion of dulcamara results in copious hydrorrhea from the nose. Belladonna causes a dryness of the pharyngeal mucous membrane. Blennostasine produces rarefaction of the nose and throat. The anesthetic effect on the pharynx resultant from prolonged use of the bromides is well known. This familiar pharmacological lore is only supplemented to the preceding pathological data for the purpose of reiterating and emphasizing that certain substances have

a penchant for exerting notable effects upon the mucous membranes of the nose, mouth and throat, or one or all of them.

In view of the foregoing confirmed knowledge it would not be chimerical to assume that certain autogenous poisons, such as result from intestinal putrefaction and absorption, might be a common cause of excretory irritation in the upper air-passages. Contemporary internists are giving extensive attention to the intestinal fermentative and putrefactive processes and their effects upon the circulatory apparatus. To discuss the biochemistry of these ferments would transcend the province of this paper, and would encroach on a domain which is being skilfully explored by competent investigators. Dwelling on this phase but superficially, one might review that skatol, indol, phenol, and other end products of intestinal putrefaction enter the blood and lymph streams. Many of the familiar migraines and headaches are resultant forms of the disturbances created by these poisons. It is irrelevant to our thesis whether these irritants exert their noxious effects centrally, thus producing derangement of the innervation and consequent stasis, or whether they exert their afflictive outbursts directly, metaphorically assaulting their host at the moment of their separation from his hospitality. It is principally desired to set up the postulate that the mucous membranes of the upper respiratory passages are eliminative organs for substances resulting from metabolism, which substances circulate in the blood or lymph-currents, or both, in a manner akin to similar processes taking place during the course of certain diseases and after the ingestion of various pharmaceutical substances. Applying this postulation to the exasperating array of patients suffering with so-called chronic rhinitis who "make the rounds" without deriving more than temporary relief, it might not be amiss to transiently consider the local treatment a secondary element, and concentrate our efforts on the segregation of the "vera causa."

The "colds in the head" following dietetic and bibulous indiscretions are familiar instances of misnomers. Supplementary to this hypothesis comes the suggestion that we, while not altogether ignoring, should at least cease to concentrate our attention on the interior of the nose of patients who are sufferers from hay-fever and allied disorders. The fact that such persons, having no demonstrable anatomical nasal abnormality, on migrating to a salubrious zone, are promptly relieved of their distressing symptoms, has tended to fortify us in the belief that the etiology of their ailment is simply extraneous. Yet it is conceivable that such persons perennially excrete, intranasally, polymorphic substances, which, in the flowering season, unite chemically with certain pollens then extant, thereby forming a product inherently irritating to the mucous membrane on and in which such chemical reaction is taking place.

There is here a broad field for original investigation, and any medical Alexander who is weeping because there are no further worlds to conquer may forthwith dry his tears. A decade hence "eliminative treatment," as still in vogue, will be ridiculed as we now scoff at Baunscheidtismus. Metchnikoff has pointed the way, and many of his disciples are plodding along numerous, divergent paths. Among the promising agents are some of the laboratory products based upon salicylic acid. Theoretically one can conceive of chemicals or enzymes that would retard or even prevent objectionable intestinal fermentation without coincidentally impairing the physiological digestive and eliminative functions. The arrival of this desideratum will mark an era in the therapeutics of rhinology.

## DERMATOSES DUE TO TOXEMIA.

By BENJAMIN F. OCHS, M.D.,

NEW YORK.

ADJUNCT DERMATOLOGIST LEBANON HOSPITAL; INSTRUCTOR IN DERMATOLOGY, FORDHAM UNIVERSITY; DERMATOLOGIST, LEBANON AND HARLEM HOSPITALS, O.P.D.

Just as in the acute infectious diseases, as measles, scarlet fever, typhoid fever, etc., there are cutaneous manifestations, so certain forms of autotoxemia have skin lesions; in fact, it is a question whether or not the skin manifestations are not the prominent symptoms of this class of diseases. Thus we have a number of diseases which are classed as toxic and which have cutaneous lesions. These lesions are of great importance, and often prove the etiology of the disease. We find that certain forms of eczema, especially in childhood, are due to an autotoxemia. We also find that many cases of urticaria are due to the same cause.

Eczema, while not entirely due to a toxic condition, is greatly aggravated by anything which tends to disturb the digestion; thus a dyspepsia or a gastrointestinal irritation cannot alone cause an eczema, but will greatly aggravate an already existing one. Probably the toxins act upon the nerve endings in the skin and cause these disturbances. We see in children a certain form of eczema which is entirely cured by administering calomel or any purge to clear the intestinal tract. We find that children thus affected are those who do not, or rarely ever vomit, and, if by any chance vomiting occurs, such children have their cutaneous lesions disappear without any medication at all. Is not this a proof that it is due to a toxemia? Should, however, these children not vomit spontaneously, a simple calomel or any other purge, and cutting down the amount of and the number of feedings, frequently suffices to cure them. Too much stress cannot be laid on the fact that these children, as a rule, do not vomit. We have repeatedly seen in dispensary practice that children with well-marked facial eczema get entirely well under this simple form of treatment. Does not this bear out the statement that these eczemas are due to the toxins? Urticaria, all admit, is frequently caused by intestinal disturbances. Here evidently something ingested brings on a toxic condition, and we have the reflex symptoms on the skin.

The wheals, at first small, are irritated by scratching, grow larger, and cause the patient a great deal of discomfort. Many of these cases are promptly arrested by a thorough purge. Is not this the case of urticaria caused by shellfish?

We see such cases quite frequently in the summer. Why some patients will get ptomaine poisoning while others get an urticaria, we do not know. We know, however, that this occurs. In a family eating the same kind of food, one will get a bad attack of the hives, while another will get ptomaine poisoning, and as both conditions are relieved by thorough purging does it not prove that the skin manifestation is the direct result of the toxins?

Not only is this true of shellfish—in which a decomposition could be accused to be the cause—but it is also true of many other kinds of food, such as

berries, particularly the strawberry, of cheese, bologna sausage, etc.

Another cutaneous eruption caused by toxemia is acne. We know we are now treading on dangerous ground; but who has not seen a case of acne aggravated by coffee? Overeating, eating indigestible food, overindulgence in alcohol, smoking, etc., are quoted as etiological factors in acne. Why should a person with normal skin be able to ingest these articles of food, while those affected with or having a tendency toward acne are not able to do so? Is not a toxemia responsible for it? Why is it that these patients break out anew when they partake of ice cream, which is certainly easy of digestion? Is it not due to the toxins formed by such food and which shows itself as a reflex symptom on the skin?

Rosacea is certainly aggravated by taking tea, alcohol, etc., and is greatly aggravated by gastro-intestinal disturbances and dyspepsia.

In this connection we might add that in many other diseases toxemia keeps up or aggravates the original lesions. Thus Bulkley believes that meat is responsible for aggravating an existing psoriasis. Lichen planus certainly yields more readily to a vegetable diet. Why should this be so? We do not know. We believe that such foodstuffs are easily digested, do not cause any irritation, and that no toxins, to cause continued irritation, are formed. Why is it that certain drugs act badly on certain people? Why should the iodide cause acne in some, and the bromides, quinine, etc., cause dermatoses? Is it because a toxic condition toward such drugs is responsible for this? In certain constitutional diseases we have accompanying cutaneous lesions: thus in rheumatism we have the purpura, the erythema nodosa, etc.

We see from the foregoing that while these diseases are classed as dermatoses they are really reflex symptoms of a condition originating within the organism, and we have come to the conclusion that while not all, the majority are only reflex symptoms of toxemia.

## Medicolegal Notes.

**Employment of Physicians by Injured Man's Employer.**—In an action for professional services rendered to an employee on the defendant's ranch it appeared that the employee had his leg broken by a horse falling on it. After temporary treatment the defendant decided to send the injured man to a certain sanatorium, and sent him there in charge of another employee with a letter addressed to doctors in the vicinity of the sanatorium. There he was treated by Drs. Lumpkin and Thomas, who charged $110 for their services, which was shown to be a reasonable charge. The only question was whether the plaintiffs were employed by the defendant. He testified that his letter, which had been lost, was addressed to Drs. Walker and Johnston. Dr. Walker, who assisted in the operation, testified that it was addressed to Drs. Walker, Johnston, or Thomas. It was held that the jury were justified in finding that the plaintiff's messenger requested Lumpkin and Thomas to treat the case, and that the court did not err in submitting the question of whether the messenger was acting within the apparent scope of his authority. The defendant testified that before the injured man was discharged from treatment the defendant informed the plaintiffs that he would not pay them, as he had not employed them, and he requested the court to charge the jury that they could not allow the plaintiffs anything after such denial of liability. Had they quit the case it would, under the statement of the defendant then made, have amounted to an admission that they were never in his employment. The jury having found that the plaintiffs were employed to treat the case, it was held that that employment continued while the case demanded their services or until they were discharged by the defendant. Judgment for the plaintiff was affirmed.—Gray v. Lumpkin & Thomas, Texas Civil Appeals, 159 S. W. 880.

**Minor Child—Necessity for Parent's or Guardian's Consent to Anesthetic and Operation.**—A child of eleven years of age was taken by her adult sister to a surgeon, who, without the knowledge of the child's parents, who could easily have been communicated with, permitted the surgeon to anesthetize the child for the removal of adenoids. There was no emergency, and the life of the child was not dependent upon the operation. During its performance the child died. In an action for the death it was held that the child had no authority to consent to the performance of the operation on its own behalf. The sister's authority depended on whether the parents' authority had been delegated to her. In the absence of any evidence to that effect, the performance of the operation by the surgeon was unlawful, so as to warrant recovery for the death of the child, independent of the question of negligence in the performance of the operation. The law, said the court, as enunciated by the few courts which have passed thereon, is not as clear and satisfactory as it should be in cases of this character, but it seems to be reasonably established that a physician is liable for operating upon a patient unless he obtains the consent of the patient, if competent, and if not, of some one who under the circumstances would be legally authorized to give the requisite consent. Of course consent may be presumed from circumstances, without direct proof, but there must be consent in every case, except in an emergency when to delay to obtain consent would endanger the life or health of the patient. A child of tender years being incapable of legally consenting to the administration of an anesthetic and a surgical operation, consent must be obtained from the person clothed with authority to consent by the law, which would be the parent or guardian, in case there be such person. Under the circumstances of the present case, the sister, whether adult or otherwise, would have no more authority by virtue of such relationship than would any other person, and it was fundamental error upon the part of the court to instruct the jury that the presence of the elder sister, as a matter of law, justified the physicians in performing the operation. The parents were easily accessible by telephone or telegraph, and there was no emergency. The question of consent of the parents was held to be one of fact which should have been submitted to the jury. Judgment for the defendants was reversed and the cause remanded.—Rishworth v. Moss, Texas Civil Appeals, 159 S. W. 122.

**Degree of Skill and Care Required.**—In an action for malpractice the trial court instructed the jury: "If the defendant, at any stage of the treatment of the plaintiff, or at any time during his employment, failed to do what physicians and surgeons usually and generally in this locality would have done in the treatment of her, and because of such failure there was an unfavorable result, then the defendant would be liable to the plaintiff for the damages occasioned by such failure." The instruction was held to be faulty in that it made the standard of treatment that of the locality alone in which the defendant was practising, whereas the true standard is that of all similar localities. But the error was no more prejudicial to the defendant than to the plaintiff. Judgment for the plaintiff was reversed because of the trial court's erroneous refusal, on the ground of want of power, to exercise its discretion to grant a new trial for improper and inflammatory argument of the plaintiff's counsel.—Cranford v. O'Shea, Washington Supreme Court, 134 Pac. 486.

**Malpractice—Tort or Contract—Limitation of Action.**—A complaint alleged that the plaintiff employed the defendant to set, adjust, care for, and heal a dislocated hip joint from which the plaintiff was then suffering; that the defendant undertook to set, adjust, care for, and heal said joint; that the defendant negligently and unskilfully conducted himself in the treatment of said injury, whereby the ligaments and muscles surrounding said joint became inflamed, weakened, and diseased, so as to make the plaintiff a cripple for life. The complaint was held to state a cause of action, and the action, being one based on breach of contract, fell within the six-year limitation applicable to actions upon contracts.—Finch v. Bursheim, Minnesota Supreme Court, 142 N. W. 143.

## DIABETES INSIPIDUS.

FOR a long time diabetes insipidus was a sort of medical curiosity and though Willis recognized a non-saccharine form of diabetes as long ago as 1674 it is only recently that attempts to solve the problem of its causation have met with any distinct success. Professor Erich Meyer has recently published* an excellent résumé of the work that has been done on this condition. Examination into the inevitable association of polydipsia with polyuria has revealed the fact that the causes of diabetes insipidus, so-called, can be divided into two groups, one in which the polydipsia is primary and the polyuria merely the effect of the increased ingestion of fluids, the other, which may be called the true diabetes insipidus, being a primary polyuria with polydipsia resulting from the dehydration of the blood.

The differentiation of these two types is attended with marked difficulties, and since in many of the patients there is marked psychic disturbance one exasperated investigator announced the conclusion "omnis diabeticus mendax." It was thought at first that in a primary polydipsia there would be a dilution of the blood while in the primary polyuria the blood would become more concentrated. Investigation showed that the ingestion of large quantities of fluid caused on the contrary a concentration of the blood. This apparently paradoxical effect is explained by the fact that when the water intake is markedly increased the output of sodium chloride is increased along with that of water. In order to maintain the constant salt content of the blood, therefore, the latter must continue to be concentrated until enough salt can be absorbed from the tissues to restore the normal conditions.

More progress has been made by obtaining accurate and complete histories of the patients and subjecting them to painstaking observation. In this way it has been noted that primary polydipsia is usually associated with certain psychic anomalies, such as hysteria and paranoia, phobias, etc. The patient has certain insane ideas, and as a result of them is led to drink large quantities of water. These patients may be classed as cases of false diabetes insipidus, and it is sometimes possible to bring about a cure in them by the application of the methods of psychotherapy.

Primary polyuria seems to be closely associated with an abnormal stimulation of the kidneys by the central nervous system without the presence of any psychic disturbances. Claude Bernard showed that injury to the floor of the fourth ventricle in animals resulted in a polyuria. This injury causes a stimulation of the sympathetic, and the polyuria takes place in thirsting animals. It can be prevented by section of the splanchnic nerve. So in the genuine diabetes insipidus Forschbach and Weber have concluded that the kidney excretes a large quantity of water because of abnormal stimulation which is possibly distributed through the sympathetic system.

The primary polyurias have been divided into the idiopathic, and those due to disturbances in the central nervous system. The latter are due to cerebrospinal lues chiefly, but may be associated with hydrocephalus, brain tumor, disturbances in development, or affections of the hypophysis. So far as the idiopathic variety is concerned, it can only be said that in them there has been a failure to demonstrate the primary condition, and it is probable that with better facilities and more knowledge this group will in time be abolished. Whatever the cause, this abnormal stimulation of the kidney seems in time to bring about a weakening of its ability to concentrate the urine. This led at one time to the statement that no patient who could be forced to excrete a urine of a high specific gravity suffered from diabetes insipidus. This disturbance has, however, been shown not to be absolute. Almost all of these patients can be influenced so as to excrete a concentrated urine, and will do so sometimes when suffering with a fever. The administration of theophylline will sometimes bring about the same result.

The effect of this increase in the water metabolism has been found to be very slight. There is no such thing as a "water heart" which corresponds to the beer heart, and the latter is probably due to the alcohol and extractives in the beer. There is no increase in the blood pressure, no cachexia develops, and there is no alteration of the salt or nitrogenous metabolism. The diabète azoturique of the French is associated with and probably due to the polyphagia.

The course, prognosis, and treatment of this condition will naturally depend upon the etiological factor in any instance. Feilchenfeld, Leick, and Stein have recommended injections of 1/12 to 1/6 grain of strychnine nitrate, while the experimental results obtained with theophylline, and other diuretics of that class would be sufficient warrant for their trial. The gradual diminution which has taken place in the idiopathic group, however, should stimulate the observer to a thorough search for the cause which will probably be found; but the differential diagnosis is not easy and this, coupled with the comparative rarity of the condition, will probably delay the solution of the problem for a long time to come.

*Über den gegenwärtigen Stand der Pathologie und Therapie des Diabetes insipidus. Von Professor Dr. Erich Meyer, Vorstand der medizinischen Universitäts-Poliklinik Strassburg i. E. Price M. 1.50. Halle a. S.: Carl Marhold, 1914.

## WORK OF THE BUREAU OF HEALTH FOR THE PHILIPPINES.

THE report concerning health conditions in the Philippines, issued recently, shows that steady progress has been made in freeing those islands from the diseases which are the bane of all tropical countries. The report is, in a high degree, a strong argument for leaving the control in the hands of the Americans instead of turning it over to the Filipinos, and signifies the triumph of the existing plan of organization devised and carried out by the extremely capable Director of Health, Dr. Victor G. Heiser, and his efficient coworkers. Health conditions throughout the island during the fiscal year, July 1, 1912, to June 31, 1913, have been excellent. No serious epidemic of disease occurred, with the exception of isolated cases of plague in the city of Manila. It is pointed out, however, in the report, that even better results would have been obtained had more money been available. On the other hand, owing to the aid received from practically every branch of the Government in promoting health work, money has been made to go much further in attaining successful results than would have been the case elsewhere.

That good health is, to a very considerable extent, a purchasable commodity has been proved on several occasions in the Philippines. Thus, for example, the installation of artesian wells produced a definite reduction in the death rate and a great improvement in the sick rate in communities in which such water was used. The regular use of quinine among the inmates of the Iwahig Penal Colony clearly demonstrated the prophylactic value of this remedy, for, in spite of the fact that malaria of the most severe type is present on all sides and causes a heavy death rate, yet the inmates of the colony are as healthy as the people of New York. The elimination of intestinal parasites among a given thousand inhabitants produces a marked improvement in general health. In Manila, despite the constant importation of smallpox, from which disease formerly hundreds died annually during the period under review, there has not been a single death from this disease, because the population is kept thoroughly vaccinated. Referring to the milk supply of Manila, it is stated that the constant efforts of the Bureau of Health have not been successful in greatly improving the quality of fresh milk. Fortunately the last Legislature made an appropriation to the Society for the Protection of Infants for the construction of a building for housing the milk-sterilizing outfit which was presented by Mr. Nathan Straus, through the efforts of the Bureau, and as soon as this becomes available it is proposed to require that all milk in the city of Manila be pasteurized before it is sold or offered for sale.

Interesting experiments as to the menace of pigs in the transmission of certain diseases were made during the year. The conclusions reached were that experiments made to determine whether or not hogs might be carriers of the cholera vibrio and dysentery bacillus met with negative results. Dr. E. L. Walker, the acting chief of the biological laboratory, has reported that it is possible to distinguish between pathogenic amebas and the ordinary water ameba and that this latter form is harmless to man. Notwithstanding this finding, in order to be on the safe side the only course to pursue is to use only water that has been boiled, distilled, or otherwise made safe; not to use low-growing garden vegetables in a raw state; and to insist upon cleanliness of the hands of those who are engaged in the preparation of food.

The question of beriberi and its prevention is naturally dealt with somewhat exhaustively, for with the possible exception of the plague it has been responsible for more deaths in the Orient than any one disease. Moreover, beriberi has been the means of rendering many thousands chronic invalids, and as it more often attacks the strong, it bulks large from the economic standpoint. According to the report this terrible disease may be entirely prevented in the Philippine Islands without increasing the cost of living. By simply substituting unpolished rice for white rice, there is every reason to believe that its complete disappearance can be effected.

It was mentioned in the last annual report that at Peñaranda, Nueva Ecija Province, among a population of 8,410 there had been found forty-three cases of goiter and that the water supply was under suspicion. District Health Officer Fernandez was instructed to make a careful investigation and, if possible, to make some experiments along the lines of those made by Dr. Robert McCarrison and reported some time ago in the *Lancet*. Dr. Fernandez has made a preliminary report in which he states that the use of artesian wells has now become quite general in Peñaranda and that he has been unable to find any new cases of goiter during the past year. Insanity in the Philippines is comparatively rare, statistics seeming to show that it is six times more prevalent in the United States than in the islands, but provision for the insane is very inadequate.

With regard to the treatment of leprosy, and as the result of numerous experiments made by the Bureau with the chaulmoogra-oil method of treatment the report states that so far the outcome has not been such as to warrant the belief that a specific for leprosy has been found. Still, it is thought that, if adequate funds were available for the opening of a laboratory for the study of this treatment and an attached hospital provided for making accurate observations, at least a way has been indicated which might eventually lead to success. Malarial fever still exacts a heavy death toll in Manila, statistics showing that in round numbers 25,000 deaths occur annually from this disease.

Plague has been fairly prevalent in certain parts of the Islands and in Iloilo owing to the absence of rat plague and to the fact that the disease yielded readily to isolation and disinfection, it has been suspected that its origin may have been due to bedbugs. Typhoid fever was widely prevalent in the Philippines in the period covered by the report. Yaws was treated with almost invariable success by salvarsan.

The entire report supplies convincing proof, if such proof were required, of the energy, wisdom, and skill evinced by the members of the Bureau of Health of the Philippine Islands and provides an instructive commentary on the action of those who would for political purposes displace a Bureau of which the organization has been built up to bring about results so strikingly successful. It is a matter which certainly leads one to question seriously whether, in any event, politics should be allowed to enter into and prejudice affairs which directly concern the health of a population. *Salus populi suprema lex* is a motto which should stand forever.

## PERIODS OF STRESS IN HUMAN DEVELOPMENT.

In the Section of Stomatology, International Congress of Medicine, held in London, last July, a paper on periods of stress in human development was read by Dr. Eugene S. Talbot of Chicago (*Medical Press and Circular*, December 17, 1913). The speaker pointed out that the embyronic history of man as well as the lower vertebrates is essentially the same as that of the invertebrates. The differentiation lies in the development of some structures and the sacrifice of others for the benefit of the organism as a whole. In the process of development from the primitive cell, periods occur in which unfavorable influences act so as to occasion a stress or struggle. If the stress falls on one organ local changes may result in arrested or excessive development, that is in the degeneration of the particular organ. Three kinds of unfavorable influences affect the organism or its parts, the mechanic, toxic, and nutritive.

Struggle for existence on the part of the different organs and systems is most ardent during periods of evolution and involution. For instance, a check or an excess of growth of the higher organs of the nervous system frequently results in impairment of the mental faculties to the extent that any of the degenerations may occur. In these cases the brain remains in the stage characteristic of the common simian ancestor, or the higher faculties may attain only the development of primitive races in whom emotional control and ethical ideas are insufficient to meet the exigencies of civilized states. The power of passing through the fetal periods of stress depends upon the condition of the fetal organs at the time of these periods stress, partly on inherited factors and partly on maternal conditions.

During the entire developmental life of man extending over the first thirty years, there are marked changes in the nervous system and associated organs. There is constant demand on the powers of nutrition. The first period of stress is infancy. The second period involves a series of changes which occupies the time from six months to two years after birth. The second dentition, beginning with the sixth year, forms the third period of stress. The fourth period is ushered in by puberty, and finally the climacteric period, marked in women about the fifth decade, and the failure of the sexual powers in man, coming somewhat later, necessitate readjustments of metabolism of great importance to all organs, and note the fifth period of stress. The last period is that of decadence and senility. The author emphasizes the importance of periods of stress in the development of the human fetus, laying much emphasis on the fact that the greatest care and protection as well as careful study should be given to parent and child so that degenerative influences may not lessen the chances of survival or aid in furthering the degenerative tendencies of the human race.

## A Unique Case of Pluriglandular Insufficiency.

At a recent session of the Charité Hospital, Berlin, Maase presented a genuine case of this condition with autopsy finds (*Berliner klinische Wochenschrift*, January 19, 1914). The patient was a Russian girl aged twenty-four, of epileptic and diabetic ancestry. She had been normal in every way up to the age of eighteen years, when she developed ophthalmoplegia. When approximately twenty years old she developed a sort of myxedematous state, attended by suppression of the menses. A physician found glycosuria, and a positive Wassermann reaction. Later the author discovered a spinal curvature. The progress of the case suggested myxedema to the exclusion of other affections. At the same time there was a shrinkage in the body measurements represented by various deformities. The bone condition developed some resemblance to osteomalacia. Death occurred unexpectedly from erysipelas, thereby giving an opportunity for autopsy. Radiography had shown a normal sella turcica, but the hypophysis, normal in size, was adherent to the bone, and of firm consistence. Thymus remains were quite abundant, while the thyroid was abnormally small in both lobes. The pancreas was small, consisting largely of fat and connective tissue. The adrenals were normal to the naked eye. The ovaries were abnormally small and showed no Graafian follicles. The bones were very much thinned and brittle. The liver was fatty. The other organs were normal save for the heart which exhibited the changes to be expected after death from erysipelas. The author explains his case on the assumption that the condition of the thyroid was responsible for myxedema and possibly for certain psychic manifestations, but beyond that he could not go, save perhaps to hold the abnormal pancreas responsible for the diabetes. The adrenal bodies alone of all the endocrinous glands were normal, so that the case may be termed subtotal. In no other similar case reported has there been glycosuria.

## News of the Week.

**Oldest Indian Dead.**—White Eagle, chief of the Ponca tribe, and said to be the oldest Indian in the United States, died at his home in Ponca City, Okla., on February 5, aged 111 years.

**Bavaria in Radium Market.**—The Bavarian Parliament on February 5 appropriated the sum of $150,000 for the purchase of radium with which to treat the poor suffering with cancer.

**Physicians Win in Russia.**—All restrictions on the length of sojourn to be permitted in Russia to Jewish physicians who desire to attend the Twelfth International Ophthalmological Congress in St. Petersburg this summer have been removed by order of the Russian Minister of the Interior. The members of the congress, without exception,

have been assured unrestricted admission and unlimited sojourn within the boundaries of the empire. The congress will convene on July 28 and remain in session until August 2.

**State Health Board Appointments.**—Dr. H. M. Biggs, the new State Commissioner of Health of New York, has appointed Dr. Augustus B. Wadsworth of New York to be Director of the Division of Laboratories and Research, and Dr. Henry L. K. Shaw of Albany to be Director of the Division of Child Hygiene of the State Department of Health.

**Harvey Society.**—Prof. J. J. R. Macleod of Western Reserve University, Cleveland, O., will lecture on February 14 at 8.30 o'clock before the Harvey Society at the Academy of Medicine, New York, on "Recent Work on the Physiological Pathology of Glycosuria."

**Gifts to Charities.**—By the will of the late Jane S. Echternach of Philadelphia bequests are made as follows: Women's Southern Homeopathic Hospital, $19,000; St. Luke's Homeopathic Hospital, $14,000; Women's Homeopathic Association of Philadelphia, $5,600; Philadelphia Home for Incurables, $5,000; Children's Seashore House, Atlantic City, $5,000; Germantown Hospital, $2,800; Wills Eye Hospital, $2,800; Hahnemann College and Hospital, $2,800; Pennsylvania Epileptic Hospital and Colony Farm, $2,800 and Free Hospital for Consumptives, $2,800.

By the will of the late Anna T. Jeanes of Philadelphia, the sum of $2,000,000 is set aside for the establishment of a hospital as a memorial to the testator. The money was originally devised to Swarthmore College on condition that athletic sports be abolished in that institution, but the gift was declined, and the money has reverted to the Yearly Meeting of Friends, to which $200,000 had originally been bequeathed for the founding of a hospital. Dr. James Tyson is one of the incorporators of the projected hospital.

The New York Post-Graduate Medical School and Hospital receives a bequest of $1,000 by the will of the late Miss Emily Chamberlain of this city.

By the will of the late Lord Strathcona, the sum of $25,000 is left to the Right Hon. John Burns, for the purpose of maintaining a home for lepers in the United Kingdom, but none of this is to be expended for other lepers who may come into the kingdom; $50,000 is given to the maintenance of the Leanchoil Cottage Hospital, Forres, as from Lady Strathcona and the Queen Alexandra Home and Hospital for Incurables, the North London or Paralytic Hospital, the London University College Hospital, and the Middlesex Hospital receive $10,000 each.

**Matteawan Overcrowded.**—The capacity of the Matteawan State Hospital for the Criminal Insane has recently been so greatly overtaxed that the superintendent is considering the advisability of refusing to accept any more persons from New York County, which sends a large proportion of the patients. There are at present eight hundred inmates in the hospital, the largest number in the history of the institution.

**Abolish Board of Food and Drug Inspection.**—In the interest of efficiency and economy, the Board of Food and Drug Inspection of the Department of Agriculture has been abolished by Secretary Houston, and the appeals which formerly went before the board will in future be submitted to Dr. Carl Alsberg, the successor of Dr. Wiley. Dr. Alsberg will be assisted by Dr. R. L. Emerson of Boston. Under this plan the enforcement of the pure food law will be virtually in the hands of one man. The country will be divided into three inspection districts with Washington, Chicago, and San Francisco as the respective headquarters. This concentration of the authority of enforcement was one of the things for which Dr. Wiley contended.

**Friedmann Cure Banned Again.**—The Board of Health of New York City, which is now composed of Health Commissioner Goldwater, Police Commissioner McKay, and Health Officer O'Connell, has approved the action of the former board in refusing to permit the use of the Friedmann turtle bacillus culture in this city. Application was recently made by Dr. Hans Karfunkel, a physician of Berlin, for permission to introduce something which he claims is a modification of the Friedmann remedy, but the board denied the application. The United States Treasury Department has recently denied the statement that the Piorkowski Laboratories of Berlin, Germany, have been licensed by the department for the importation and sale in this country of "turtle tuberculin." On the contrary, such a license, when applied for, was, after an inspection of the establishment, specifically refused.

**Grading of Nurses.**—The Committee on the Grading and Classification of Nurses appointed by the American Hospital Association, desiring to bring the subject to the attention of medical men, has prepared the following list of questions which it submits with the request that answers thereto be sent to Dr. Renwick Ross, Buffalo General Hospital, Buffalo, N. Y., before April 15. (1) In your opinion is it possible to meet the nursing needs of the average community in city, town, and country in the United States and Canada with graduate nurse service alone? (2) If in your opinion only graduate service should be used, will you kindly present an outline of a practical comprehensive program for supplying graduate service to all classes needing continuous nursing? (3) If more than one grade of nurse is a necessity, will you please state how many grades you consider necessary? How would you classify nurses so as to include in your classification all who nurse for hire? (4) Will you kindly suggest a substitute term for the grade B or "certified nurse" as recommended by the committee on grading of last year, if you consider that some better term should be used to designate nurses trained in special hospitals or hospitals unable to give a full training. Please state whether or not you are satisfied with the distinctive terms recommended by the committee of last year. Give briefly your reasons if not satisfied. (5) If several grades seem to be necessary, how and where should the several grades be trained? (6) In view of the fact that many tuberculosis hospitals find it impossible to secure sufficient graduate nurses to care for their patients, what measures would you suggest for meeting the nursing needs in such institutions? (7) If training is given in a tuberculosis hospital, how long should the course be and how would you classify those completing such a course? (8) In view of the fact that there is a constant and pressing demand for maternity nurses in homes of moderate means, what measures that are practicable for the average com-

munity would you suggest for meeting this need? How classify such nurses? (9) What constructive recommendations would you make with a view to improving on the plans presented by the committee on the grading of nurses in the report submitted to the Association at the Boston convention, a copy of which was mailed to each member? (10) Will you kindly suggest to the committee of this year any feasible plans which occur to you for improving the quality of home nursing now being received by those who cannot afford graduate nurses?

**Women Internes Urged.**—The question of appointing women physicians as internes at the Metropolitan Hospital, Blackwell's Island, N. Y., is under consideration by the Commissioner of Charities. At present, examination for these positions are open to men only, and the medical board of the hospital recently passed a resolution requesting that the privilege be extended to women. It is felt that a year's hospital training will soon be required of every graduate of a medical school before a license to practise medicine is issued, and that opportunities for training should be afforded to the many women now entering the profession.

**Expense of Alien Insane.**—In a special message to the Legislature, Governor Glynn of New York recently called attention to the great cost of caring for the alien insane in New York State. He believes that the Federal Government should relieve the State of this burden. There are now about 9,241 aliens in the insane asylums of New York, and the cost of caring for these for ten years, the average length of confinement, is estimated at $25,000,000.

**To Bar Sale of Drugs.**—The Senate and Assembly Committee on Health of the New York Legislature has under consideration a bill requiring stringent regulations for the sale of opium, morphine, and all their derivative salts, including heroin, and all other habit-forming drugs. A bill to prevent the sale of tablets of bichloride of mercury except on a physician's prescription has also been introduced into the Legislature.

Following their conviction for selling heroin to boys in New York City three men were sentenced in the Court of Special Sessions on February 3, to serve six months each in the penitentiary, while a fourth man was sentenced to serve one year.

**Central Council of Public Health.**—A new organization having for its aim to serve as a clearing house for all ideas for the improvement of health conditions in New York City, to obtain and disseminate information toward this end, and to coordinate the work of the different institutions doing public health work and prevent duplication of their efforts, was formed at a meeting of representatives of many private organizations at the Academy of Medicine on February 4. The organization is to be known as the Health Federation of the City of New York, and its advisory body, the membership of which is to be limited to fifteen, as the Central Council of Public Health. The members of this council so far announced are: Dr. John H. Huddleston, Chairman; Bailey B. Burritt, Acting General Director of the Association for Improving the Condition of the Poor; Dr. Charles Loomis Dana, Chairman of the Public Health, Hospital, and Budget Committee of the New York Academy of Medicine, and of the Public Health Committee of the City Club; Homer Folks, Miss Pauline Goldmark of the Governing Board of the Consumers' League, James Jenkins, Jr.; Dr. Edward L. Keyes, Jr.; Dr. Philip Van Ingen, Medical Advisor of the New York Milk Committee; Miss Lillian D. Wald, Chairman of the Committee on Public Health of the Settlements; Prof. C.-E. A. Winslow, and Dr. E. H. Lewinski-Corwin, Executive Secretary.

**Ehrlich on Radium.**—Prof Paul Ehrlich of Frankfort, who has recently been spending his vacation in Paris, is quoted in the newspapers as having said: "I am convinced that the next ten years will see immense progress in the treatment of contagious diseases by radium and the *x*-rays, which are still imperfectly investigated. Perhaps cancer will be conquered. The new discoveries will be along the lines of chemicoradiotherapy. Vaccines and prophylactic serums, it seems to me, have yielded all that there is to be obtained from them."

**Smallpox in Pennsylvania.**—Ninety cases of smallpox have developed at Northeast, a town of 2,000 inhabitants in Erie County, Pa., and as a result fifty-five houses have been quarantined and all the inhabitants of the township in which Northeast is situated have been quarantined.

**Investigate Health Department.**—The Bureau of Municipal Research of New York has recently issued a criticism of the methods of the City Department of Health in handling cases of typhoid fever and in making investigations of milk. It is charged that the epidemic on the east side of the city last fall could have been prevented had the lessons of the epidemic of 1911 been properly applied. The bureau submitted detailed reports of its findings and recommendations to Dr. Goldwater on his assumption of the duties of Health Commissioner on February 1.

**Christian Scientists Held.**—Following the death of a nineteen-months-old child in New York recently, two Christian Science "healers" who had treated him were held for criminal negligence by the Coroner's jury. The child died from diphtheria.

**Self-Laudation Rebuked.**—At a meeting of the Medical Society of the County of New York last week, a report of an investigation made by the Comitia minora at the request of the Board of Censors, was read. In it attention was called to "the rapidly increasing number of publications in the lay press concerning the professional activities of many prominent members of the society," which were described as "self-laudation rather than public health education." While admitting the right of the public to receive information on the progress of medical science, the report stated that what was printed "should be the substantial truth, and not the possibly immature ideas of an enthusiast, who may awaken false hopes, and by the unsuccessful outcome of his efforts lower the confidence of the public in the profession." At the close of the reading of the report, the Society unanimously adopted resolutions requesting that its members when giving information to the lay press do so in an impersonal manner, and in strict conformity with the well-known principles of medical ethics.

**Rural Death Rate High.**—The New York State Grange at its recent convention in Poughkeepsie recommended the establishment of a division of rural hygiene in the New York State Department of Health. This action was taken following a

report from the health committee in which it was pointed out that while the death rate in New York City has been only 13.7 per 1,000 of population, that in the country districts and small towns has been 15.4 per 1,000.

**Sex Hygiene Topic Barred.**—The school authorities of Montclair, N. J., have issued orders forbidding the teachings of sex hygiene in the public schools. The teachers are also forbidden to lend or to offer to lend books on this subject to their pupils.

**O'Loughlin Memorial.**—An emergency ward in St. Vincent's Hospital, New York, containing seventeen beds and a treatment room, will be dedicated on February 16 to the memory of Dr. W. F. N. O'Loughlin, the surgeon of the *Titanic*. Dr. O'Loughlin was well known at the hospital.

**To Force Pasteurization.**—In spite of strong protests and requests for delay, Commissioner Goldwater has determined to enforce the order of the Board of Health adopted several months ago, regarding the pasteurization of all grades of milk except the certified and guaranteed. All dealers who do not conform with the order will be called to show cause before the Board of Health on February 16.

**International Society of Surgery.**—The Fourth Congress of the International Society of Surgery will be held in New York from April 13 to 16, 1914, under the presidency of Professor Depage of Brussels. The meeting will be held in the ball room of the Hotel Astor, and it is expected that President Wilson will welcome the congress. Details of the program may be obtained from the American secretary of the congress, Dr. J. P. Hoguet, 40 East Forty-first street, New York.

**To Honor Dr. Daniel.**—The Alumnæ of the Out-Practice Department of the New York Infirmary for Women and Children will give a dinner at the McAlpin Hotel, at 7:30 o'clock on the evening of February 16, in honor of Dr. Annie S. Daniel. The speakers will be representative of the various fields of Dr. Daniel's activities, and it is hoped that on this occasion there may be gathered together many men and women who have been associated with her. The treasurer of the dinner is Dr. Ethel D. Brown of 26 Gramercy Park, New York.

**Obituary Notes.**—Dr. Edward G. Day of New York, a graduate of the College of Physicians and Surgeons, New York, in 1888, died at his home on February 3.

Dr. Thomas Richard Garlington of Rome, Ga., a graduate of the Jefferson Medical College, Philadelphia, in 1890, and a member of the Medical Association of Georgia and the Floyd County Medical Society, died at his home, after a long illness, on January 18, aged 54 years.

Dr. James L. Reilly of Chicago, Ill., a graduate of the Northwestern University Medical College, Chicago, in 1889, and a member of the American Medical Association and the Illinois State and Chicago Medical Societies, died at the Mercy Hospital, Chicago, from pneumonia, on January 15, aged 53 years.

Dr. William T. Ramsey of Cambridge, O., a graduate of the George Washington University Department of Medicine, Washington, in 1871, died at his home, after a long illness, on January 19, aged 66 years.

Dr. Robert G. Hassard of Thomaston, Conn., a graduate of the Yale University Medical Department, New Haven, in 1862, and a member of the Connecticut State and Litchfield County Medical Societies, died recently at his home, aged 71 years.

Dr. John Avery of Greenville, Mich., a graduate of the Cleveland Homeopathic Medical College, Cleveland, O., in 1850, a veteran of the Civil War, for two terms a member of Congress, and a member of the Michigan State and Montcalm County Medical Societies, died at his home from paralysis, on January 1, aged 90 years.

Dr. Edward Payson Fowler of New York, a graduate of the New York Medical College in 1855, formerly visiting physician at Ward's Island and the Hahnemann Hospital, New York, a member of the New York Academy of Medicine, the New York State and County Medical Societies, and the New York Neurological Society, and the author and translator of many medical publications, died at his home at Pelham Manor, N. Y., from pneumonia, after a short illness, on January 29, aged 69 years.

Dr. Alfred C. Girard, Brigadier-General in the United States Army, retired, and librarian of the John Crerar Library, Chicago, died in Washington, D. C., on January 31, following an operation for appendicitis. General Girard, who was 72 years of age, served for eight years in the Indian campaigns on the frontier, and as Chief Surgeon of the Second Army Corps during the Spanish War. He also equipped the general hospital at the Presidio, San Francisco, and for three years was at its head.

## Obituary.

### WILLIAM KELLY SIMPSON, M.D.,

NEW YORK

Dr. William Kelly Simpson, professor of laryngology in the College of Physicians and Surgeons, Columbia University, New York, died suddenly at his home in this city, on February 6. Dr Simpson was born in Hudson, N. Y., on April 10, 1855, and was graduated from Cornell University in 1876 and from the College of Physicians and Surgeons in 1880. In 1892 he became assistant professor of laryngology at the college, and was elected professor in 1904. He held also the positions of consulting otologist to the Presbyterian Hospital, and consulting laryngologist to Seton Hospital, St. John's Hospital, Yonkers, and the Somerset Hospital, Somerville, N. J. He was a member of the American Medical Association, the New York State and County Medical Societies, the American Laryngological Association, the New York Academy of Medicine, the Hospital Graduates' Club, and the Alumni Associations of the College of Physicians and Surgeons and of the Presbyterian Hospital.

Dr. Simpson was most skilful in his profession, being gifted to a rare degree with the delicacy of hand and surety of touch so necessary to the laryngologist. As a teacher also of his chosen specialty he was eminently successful, his strong personal magnetism and essential friendliness bringing him into unusually close touch with his classes. He had a rare personality; most humanly gregarious, endowed with abundant humor and natural high spirits, and withal sweet tempered and full of charity, his friends were legion, and he was always a welcome addition to any gathering, whether social or medical. There have been few men whose taking away has left an ache in so many hearts as has that of Kelly Simpson.

## OUR LONDON LETTER.

(From Our Regular Correspondent.)

GRESHAM LECTURES—MICROSCOPE IN MEDICINE—INSURANCE DIFFICULTIES, STATE SERVICE PROPOSED, VARIOUS MEETINGS—OBITUARY.

London, January 23, 1914.

The first Gresham lecture for this year was delivered on Tuesday at the new Gresham College, by the "professor of physic" Dr. F. M. Sandwith, his subject being "Medicine Old and New." In this first of the course of four he spoke of medicine in Sir Thomas Gresham's day when he said although there were contradictory accounts, the sanitary conditions were the cause of much ill-health in the population and constituted a hotbed of epidemics from which the country was seldom free. There was no check upon overcrowding, windows were few and those not made to open; water supply, too, was bad. Under Queen Elizabeth the Mayors and Councillors were required to introduce reforms in these matters. All through the 16th century plague was never absent from Europe and England was rarely free from it. In the first seven months of 1563 no less than 23,000 persons died of plague. Rich people who could fled from the city into the country. A vigorous quarantine was insisted upon, citizens kept isolated in their houses and when allowed to go out compelled to carry a white rod. Elizabeth took the strictest measures for protecting herself at Windsor. Stow records that a gallows was set up in the market place to hang anyone who came from London or had goods from London. Another disease at that period was smallpox, which prevailed so constantly that it was considered inevitable for everyone to contract it sooner or later. Malaria was very common. Another epidemic called ague, but which was perhaps influenza, swept the country and the mortality it caused was great. Sweating sickness also appeared and scourged the country for about sixty-six years, passing swiftly from town to town; it usually attacked the rich rather than the poor and robust young men rather than old people or children.

In the second Gresham lecture Dr. Sandwith reviewed the late International Medical Congress of which he held the scientific work had been of the deepest interest and of the highest importance to those working in different countries for tne advance of medicine. In the previous congress held in London in 1881 the sections—only 6 in the late seventies—had grown to 16 and in the last year's meeting there were 23; and it was further gratifying to notice that for the first time the government was represented at the gathering. He pointed out the advantage of medical experts meeting, inasmuch as the personal factor still exists although the modern physician is armed by many instruments of precision. The profession also had learned to look further ahead and watch for possible or probable dangers to the community. As a result protective measures were used against typhoid, smallpox, plague, diphtheria, and hydrophobia. The lecturer next entered a defense of vivisection. This country, he said, was the only one where there was a need for protest against the absurd opposition to scientific labors for the advance of medicine.

Ehrlich's address at the Congress was a description of a new treatment by its originator which could not have been discovered except by experiments on animals. He instanced relapsing fever as a triumph for the method, whereas a patient under previous plans would have seven or more periods of high fever, a single Ehrlich administration brought the temperature down, kept it down and eliminated the parasites. How was it found out and proved that salvarsan would do this? Only by experiments on animals. The result, most successful, led to use on man. In Russia, where the disease prevailed, 92 per cent. had no relapse after the first injection. In China the mortality fell from 4 to 1 per cent. and the patients only spent two-thirds of the former period in hospital. Ehrlich's patience was extraordinary. Salvarsan was the 606th arsenic compound he prepared, and neo-salvarsan he arrived at last year, the 943d. In yaws he had reported another victory. Ehrlich looks forward with confidence to achieving further advances of the highest importance within the next five years.

The presidential address of the Royal Microscopical Society was delivered by Prof. Sims Woodhead, who took for his subject the microscope in medicine. Opening with remarks on the history of his subject he said Kircher was convinced in the Seventeenth Century that disease was caused by something possessing the attributes of a living organism. But more than a century before him Fracastorius had in some observations seemed to anticipate some such separate bodies but did not speak of them as living organisms. It was, however, to Malpighi that we owed the most fruitful work of the Seventeenth century. In the Nineteenth century the idea of contagious agents, perhaps alive, occupied much attention during the thirties. In 1840 Henle concluded they must be living organisms, capable of continued, probably independent existence, having further the power of multiplying and producing certain ferments and toxins which affected the tissues by interfering with their functions or even leading to their disintegration.

Protozoology, the newest of microscopical sciences and now the most important branch of parasitology, could only have been brought into existence by the modern microscope. Malaria, parasites, trypanosomes and all protozoa had had their life histories demonstrated by the improved methods of investigation with the best microscopes. The lecturer thought if only some twenty or thirty members of this society could be turned into the medical schools to show the potentialities of the microscope there would be still further advances in medical knowledge as the facilities for investigation would be increased in the hands of thousands of workers.

The president's idea is appropriate from his chair, and it may be admitted that the more familiar every student could be made with the microscope the better, but it seems impossible for every practitioner to make advance in research work which demands all a man's time and devotion.

The Insurance Act continues to excite discontent not only in the profession but in many sections of the public. Indeed, it looks as if it might become as perennial a source of opposition as the Vaccination Acts. People who approve of national assurance find it impossible to excuse the many anomalies of the act and are joining those who plead for drastic amendments, while others declare that the act has so utterly failed as to prove the necessity for a state medical service. The advocates of this scheme are accordingly encouraged, and many who clearly discern its socialistic tendency are willing to adopt it,

though not without regret. The Faculty of Insurance began a course of lectures last week which will perhaps consider the subject in its widest aspects. The first lecture was on the "Medical Profession and National Assurance" and the chairman, Mr. Kingley Wood, remarked that medical benefit was the cornerstone of every scheme of national insurance and in every country where it had been tried the position of the medical profession had been a source of controversy. The problem he found no nearer solution anywhere than it is here today. Owing to failure of the penal system opinion was growing in favor of a state service; but many dangers were in the way, such as its becoming akin to Poor Law relief, and as there could be no free choice of doctor there could be little personal feeling between doctor and patient. Our present scheme called national was not so, for women and children were outside. He held that whatever form it eventually took the profession must be prepared to treat the whole of the industrial classes and means must be found to secure a whole-hearted service, and insured persons got the medical aid in the form that suited them best.

Sir John Collie then proceeded to give the lecture and began by pointing out defects in the act itself, in the central administration, in the local administration and inherent in the panel system. As to the act it was a mistake to set up a new body. The Local Government Board was at hand and could have coordinated clinical and preventive medicine. Among other mistakes Sir John Collie specified setting up four separate commissions and numerous local committees and all the steps taken in dealing with the profession, especially that of admitting every one to the panels, and which therefore rushed all those who could not succeed; unduly large lists of patients were allotted to men who could not do justice to them and enormous sums were spent on trivial ailments, nothing on laboratories, *x*-rays, opportunities for consultations. The list of medical appliances was cut down to a bare minimum to spare money, but nothing like the same solicitude was shown to friendly society funds.

Sir John Collie's remedy for all these and other errors was a State Medical Service, with payment by salary, to avoid competition. Those who feared the doctor would become stereotyped he bid look at other State Services—military, naval, sanitary, education. He pleaded for a State Medical Service to follow, in a way that has delighted the Socialists and encouraged others. He would put it under the L. G. B., make it attractive to the most earnest young doctors, give them laboratories and furnish them with everything needful for research, providing them thus with a career which would demand so much competition to enter it that an examination might be imposed on candidates—as if the young men he hoped to secure had not had enough of examination! The discussion has been taken up by the outside public and the newspapers are admitting different views. One of the most trenchant replies to Sir J. Collie is by Dr. H. H. Mills, vice-chairman of the Medical Sub-committee of the London Insurance Committee. He admits the scheme is illogical and incomplete but says that is just along the lines of compromise and adaptation of all our schemes. He declares the committees have built up a complex organization affecting 14,000,000 persons directly or 20,000,000 including those indirectly concerned. The chief difficulty has been shortage of doctors. But with fair payment and relief from dispensing and collecting their accounts he has no doubt this problem will soon be solved. The immediate need is linking the scheme with hospitals and other institutions.

On Tuesday there was a meeting in the Examination Hall of the Royal College of Surgeons of the four commissions (England, Scotland, Wales, Ireland), under the Insurance Act, to consider the contribution arrears, penalties, and reduction of benefits. A scheme was submitted and duly adopted. The English Advisory Committee subsequently held a meeting to consider a proposal to prohibit after five years the meetings of approved societies or their branches on licensed premises. Great diversities of opinion were expressed and no decision arrived at. The London committee yesterday discussed the question of payment of members which has been raised, and after the expression of strong opposition of members who hold it more honorable to give their services, the decision was in favor of a payment to cover expenses of travelling, loss of time, etc., so as to enable anyone to serve to whom such expenses might be deterrent. Several cases of complaints against doctors were reported by a sub-committee. One was admitted to have been when the accused doctor was ill with scarlet fever, but it deemed the applicant did not know the *locum tenens*. It was admitted that the doctor had paid the expenses involved. Another member drew attention to a complaint shown to be unreasonable and others in which it had been found that more than "adequate treatment" had in reality been given. It was referred to the Medical Subcommittee to inquire into and report on the arrangements for treatment in the London Boroughs and also to consider the question of nursing insured persons in the County of London.

Mr. H. A. Reeves, who died on the 16th inst., aet. 70, will be missed by many, although he had for some time given up practice. He filled at different times the post of Surgeon to the London Hospital and Lecturer on Anatomy in the School attached, Surgeon to the Hospital for Women, Central Ophthalmic, East London, for Children and several others. In all he was an agreeable colleague and in all proved himself an able surgeon. At the Royal Orthopedic he made good use of the opportunities and showed great familiarity with the subject in its widest aspect. He contributed to the societies and the journals many practical articles. He wrote an excellent treatise on "Applied Anatomy." His "Human Morphology" will doubtless be known to your readers and his "Bodily Deformities" deserves their notice.

## OUR LETTER FROM THE PHILIPPINES.

(From Our Regular Correspondent.)

CRIPPLING THE BUREAU OF HEALTH—CAMPAIGN AGAINST RATS—DISPOSAL OF GARBAGE—CHRISTMAS CELEBRATION AT THE LEPER COLONY—EXAMINATION OF PUBLIC WOMEN—LAXITY IN ANTI-MOSQUITO WORK.

MANILA, P. I., December 30, 1913.

THE Appropriation Bill which has just been passed by the Lower House of the Philippine Legislature carried large reductions as compared with the bill for the past year. A great decrease in the revenues and alleged high salaries of Americans are given as the causes. The appropriation for the Bureau of Health was reduced more than $263,000

United States currency. When it is remembered that the health bureau in the past has received less than $1,000,000, it will be realized that this reduction of over 25 per cent. will in all probability seriously impair the efficiency of that branch of the government. A large percentage of the million dollars that has heretofore been appropriated has been devoted to the care of the insane, the upkeep of orphan asylums, the maintenance of general hospitals and other functions which are not ordinarily classed under health appropriations, so that the actual amount available for health purposes in the Philippines has at all times been very small. The Bureau of Health for the Philippine Islands is in effect the medical department of the government and includes not only all those functions which ordinarily come under health organizations in the United States but everything of a medical and charitable nature. As the proposed bill does not reduce the appropriations for charity purposes, the cut falls almost entirely upon health activities, so that there will be available less than $100,000 for conducting the health work of the Philippine Archipelago. This sum is believed to be entirely inadequate to provide for the most urgent health needs. As the Islands are constantly threatened with outbreaks of cholera, smallpox, and plague, the prospects for holding these diseases under control in the future are not very bright if the Appropriation Bill in its present form should become a law. The bill is now before the Upper House of the Legislature, where Dr. Heiser, the Director of Health, argued for three whole days for an increased appropriation. He pointed out that the leper segregation which had been begun so auspiciously would have to be abandoned and that the large sums which had been spent in the past would probably have been spent uselessly. Vaccination, which had already saved more than 40,000 lives a year, would have to be largely abandoned and smallpox would return once more to claim its victims. He protested against the elimination of Americans who had given the best years of their lives to the service and said that the salaries of $2,000 per annum for doctors were meager enough and could not be further reduced without losing their services.

In the course of the systematic examinations which are made of rats caught in different sections of the city, a number that came last week from Nos. 417 and 419 Calle Peñarrubia in San Nicolas District were found to have buboes and subcutaneous injection, but the incubation experiments made at the Bureau of Science were negative for plague. As an extra precaution, however, a large force of rat catchers has been put to work in the above district and general anti-rat measures are being carried out. No plague rats have been found in the Philippines since September. Two cases of human plague have occurred since May last.

The conditions at the garbage plant of the Philippine Manufacturing Company, which is the concern that has recently contracted to dispose of Manila's garbage, became so insanitary that the Bureau of Health recommended to the Municipal Board that the contract be suspended until the company provides itself with the necessary facilities to dispose of the garbage in a more sanitary manner. Owing to the lack of incinerator facilities, much crude garbage was dumped on the beach, which resulted in the breeding of myriads of flies. A case of cholera made its appearance in a house located near the garbage plant and it was believed that the flies might prove an important factor in the spread of cholera. The Municipal Board took immediate action and placed the recommendation of the Bureau of Health into effect. Extensive improvements are now being made in the garbage plant and the company hopes in a short while that it will be in a position to dispose of both garbage and refuse in a manner satisfactory to the health authorities.

The large obligation which the segregation of lepers imposes upon the Philippine Government was well illustrated by the arrangements which were made in order to make Christmas for the inmates of the Culion Leper Colony a more or less enjoyable occasion. The colony now numbers approximately 3,500 persons, and a ton of candy and a ton of popcorn were sent for free distribution among the lepers. In addition, the Manila public contributed very liberally in money and other gifts, so that it was possible to give each of the inmates of the colony a Christmas present.

The dance hall ordinance, which requires the examination at regular intervals of all women who dance in public dance halls in the city of Manila, in order to ascertain that they are not afflicted with tuberculosis, venereal, or other dangerous communicable diseases, which went into effect July 1 and which was so largely nullified on account of the fact that the dance halls simply transferred their operations to points outside the city limits, is now beginning to bring about the results which were hoped for it from the first. All of the municipalities which surround Manila have now passed similar ordinances. The examinations which have been made to date show that a large percentage of the women examined suffered from venereal diseases, and it can now be definitely stated that these women were largely responsible for the great increase which has taken place in the prevalence of venereal diseases in Manila during recent years.

The antimosquito service, which has heretofore been conducted by the Bureau of Health, has now been transferred to the Department of Sanitation of the city of Manila, which has charge of street sweeping and garbage collection. In accordance with the policy of the present administration, all of the Americans have been replaced by Filipinos. The local newspapers have been filled with complaints relative to the increase in the number of mosquitos since this transfer has been made.

Dr. A. P. O'Brien of the San Francisco Board of Health has been a visitor in the city of Manila during the past few weeks.

3. The Care for Radium Therapy. S. Delano.
4. A Study of Cancer. S. W. Little.

1. **Recurrences of Ulcer of the Duodenum.**—W. J. Mayo notes that in an investigation of the results following operation on 600 cases of ulcer of the stomach and duodenum, Graham found that 81 per cent. were so relieved as to be considered cured and 10 per cent. were markedly benefited; that is, 91 per cent. were cured or improved and 5 per cent. of the remainder were moderately improved. The results in the gastric group were not as good as in the duodenal by 3 or 4 per cent. Gastrojejunostomy was the method of choice

in the larger number of cases of duodenal ulcers subjected to operation. Failure to cure and recurrences following operation can be divided into two general groups: First, failure of the operation to relieve the stomach of its acid, irrating secretions, and inadequate protection of the ulcer itself during the healing period. For the purpose of permanently closing the pylorus, C. H. Mayo introduced the method first employed in Germany, of cutting a strip from the gastrohepatic or gastrocolic omentum, leaving it attached at one end and drawing it twice about the stomach just above the pylorus, or, if the ulcer of the duodenum is sufficiently far below the pylorus the omental strip is passed about the duodenum below the pylorus between it and the ulcer. In the second group of cases, recurrence of the ulcer following gastrojejunostomy was apparent rather than real, and had its origin in improper suturing in the operation. Suture ulceration is sometimes responsible for recurrences. Experiences of this kind teach that very fine silk, not heavier than 0, should be used for gastrojejunostomy, that the bite of the suture should be as near the margin of incision as possible and that, if it is necessary to reinforce a weak suture line, interrupted fine silk sutures are advisable on such sutures used for part or the whole of the outer row. It has been the practice in the Mayo clinic for a long time to use catgut for the inner row, but it is not the inner row that gives trouble. It is the outer or musculoperitoneal suture, and W. J. Mayo has no doubt that if the order were reversed, using silk or linen for the inner row and catgut for the outer, better results would follow.

**4. Mental Defectives.**—H. A. Knox classes mental defectives under the following heads: Idiots, profound and superficial; imbeciles, low grade, medium grade, and high grade; feeble minded, low moron and high moron; characterological freaks; vagrant type, and cranks; emotional and volitional defectives. As to the popular belief that insanity is rare in mental defectives, Knox declares that this is far from the truth; insanities, periodical and otherwise, are frequent. It is seen in infancy, and in one class of cases is characterized by dullness, melancholia, excitement or mania. When one considers, says Knox, the subject of mental enfeeblement one finds one's self at some time or other wondering what should be done to prevent it. Some authorities do not think that there is any danger to our racial mentality from this source; nevertheless, strenuous prophylaxis should be instituted in the form of: 1. Restricted immigration. Knox is of the opinion that if illiteracy were a mandatorily excludable defect, ninety per cent. of our alien defectives would be automatically excluded for the next ten years at least, and a lesser percentage for all time. 2. Public education and eugenic laws. 3. Incarceration in self supporting institutions of all known defectives. 4. All children should be examined mentally when entering school and at the end of every year thereafter until their education is completed. 5. The eradication and prevention of infectious diseases, both acute and chronic protozoon and bacterial. 6. Sensible assexualization in properly selected cases.

**5. Foreign Bodies in the Appendix.**—J. W. Kennedy gives the history and reports several cases of foreign bodies found in the appendix. It is quite impossible to say, even if a foreign body is found in the diseased organ, that it is the positive cause of the inflammation. He believes that the appendix, acting as a storehouse for infection of all kinds, has a very intimate relation to many constitutional conditions for which it has not been held responsible. We must look up its relation to typhoid fever. For the past two years Kennedy has looked into its relation to enteric fever and has, at least, made this observation, that a very small percentage of patients have typhoid who have had the appendix definitely and thoroughly removed.

**6. The Modern Treatment of Chronic Nephritis.**—R. Hills sketches the modern treatment of chronic nephritis. Referring to the treatment of special symptoms, he recommends for anemia, fresh air in abundance and good food, and states that the various preparations of iron, quinine, and strychnine have been of much service as tonics in nephritis. After reviewing the many modes of treatment for this condition, the writer says that he is impressed with the vagueness of our knowledge of the proper treatment of chronic nephritis and hopes that his resumé called from various sources will arouse discussion and bring out some points of practical importance on what is surely an important subject.

**1. Accidental Injuries to the Duodenum.**—W. J. Mayo points out that the anatomic relations of the retroperitoneal portion of the duodenum are such that this organ may be injured during operations for the removal of the right kidney when there is infiltration about the pedicle causing close adhesion to the duodenum. It not infrequently happens that in such cases the vessels are torn, causing hemorrhage calling for active hemostasis. In the attempt to check the hemorrhage by using strong biting forceps the duodenum may be seized and necrosis follow the injury, with the resulting distressing fistulæ and death. The vena cava is even more frequently injured, and Mayo is of the opinion that the use of the forceps is seldom necessary until after the vessels have been caught and the hemorrhage stopped by the finger. He mentions other arterial injuries as liable to occur in operations for kidney removal. When there is not much infiltration and nephrectomy is not advisable, it is best that one should make sure that there is no opening into the peritoneum. Mayo notes the different characters of kidney tumors, especially in malignant disease involving the pelvic and calices and other structures in which the duodenum is liable to be injured even by the most expert and careful surgeon. As a rule the duodenal injury is not made manifest for several days after the operation and the fistulæ do not tend to heal. In such a case in which the fistula was large, infiltrated and without the peritoneum, Mayo would recommend a transperitoneal attack on the fistula itself before the

patient becomes exhausted, lift the descending duodenum from its bed, suture the opening, transplant a flap of omentum across the suture, and finally perform a jejunostomy for temporary feeding purposes. Such an operation, however, while easy to figure out on paper, is sufficiently difficult to make one careful to avoid the accident requiring it.

6. **Paroxysmal Hemoglobinuria.**—W. W. Young reports a case of hemoglobinuria in a man aged 45 occurring paroxysmally and closely resembling malaria. The diagnosis of paroxysmal hemoglobinuria seemed justified by the demonstration in the blood of an autohemolysin without increased corpuscular fragility. Malarial organisms were absent, the blood platelets increased. The Wassermann reaction was positive for the blood serum. Lues was denied. Young concludes that the autohemolytic substance is probably the result of luetic infection, though possibly other agencies may produce the same effect. A vigorous antisyphilitic regime appeared, therefore, advisable in the treatment, but no case in the literature of the disease has been followed up by this form of treatment to the point at which the Wassermann becomes negative.

9. **Vagotomy.**—B. L. Spitzig discusses the disorders of the vagus as affecting the abdominal viscera more especially. On account of the anatomical distribution of the vagus, symptoms of increased innervation are readily identified in the gastrointestinal tract and are perhaps the result of such activity with hypertonia of the musculature of the stomach and intestine. This is shown in the type of constipation called spatic of early and adult middle life. A tender palpable colon and the tightly contracted external sphincter are prominent signs and rectal palpation should never be omitted. In pronounced cases intermittent pain in the region of the large bowel is complained of and may be referred to the cecal region and may lead to a needless appendectomy. The descending colon, however, is more likely to show spasticity when such pain occurs. A good many patients do not complain of abdominal pain and careful abdominal examinations may reveal hypertonicity where least expected. Spitzig estimates that perhaps two-thirds of young adults are thus affected at one time or another. Pyroplasm from vagus overfunctioning may cause delay in emptying of the gastric contents and this is usually associated with hyperacidity, suggesting ulcer. While the diagnosis of pronounced cases is easy there are less manifest conditions which may, perhaps, be included and are controlled by proper treatment, such as status lymphaticus, chronic intestinal indigestion, and the mucous colitis of adults, which may not be a colitis, but due, in its early stages at least, to a central lesion, causing vagus stimulation. As regards treatment of vagotomy atropin and belladonna are the drugs upon which dependence must be chiefly placed. The correction of constipation is very important, but it should not be treated by irritating measures which might aggravate the condition. Agar is especially recommended as a natural laxative. In the mucous disease of childhood dependent upon this cause diet should be attended to, avoidance of coarse foods, protein rich in iron, and reduction of starchy products; coffee and tea should be forbidden. The treatment of mucous colitis is more difficult. Rest in bed, hot abdominal applications, and as soon as possible a regular diet should be insisted on, as these nervous patients are apt to be overabstemious.

17. **Urine Ferment Preparation.**—J. Rosenbloom describes a method of making the enzyme from yeast for use in the fermentation test for glucose and keeping it in a form in which it will remain active for weeks. His formula is as follows: Grind up thoroughly in a mortar three cakes of compressed yeast with about 200 c.c. of liquid, with constant stirring, to about five times its volume of 95 per cent. alcohol. Allow the precipitate to settle, filter and wash the precipitate on the filter paper with about 50 c.c. of ether. Allow the precipitate to dry in the air after spreading it on a glass plate. Powder and put residue in a tightly corked amber bottle. To use this powder as a ferment for urine, take about as much as the end of a medium-sized knife blade will hold, mix it thoroughly with the urine to be tested, and pour the mixture into a fermentation tube. The urine freed from protein, if present, should be slightly acidulated with 1 per cent. tartaric or acetic acid solution and later boiled to dislodge any combined carbolic acid. Control tests should also be made with normal urine to show the activity of the test and the absence of gas from self-fermentation.

5. The Tolerance of Arsenic by the Human System. H. G. A. Harding.

4. **Protein Metabolism During Starvation.**—G. Mann refers to a previous paper in the *Lancet* dealing with the changes induced in blood by feeding, in which Dr. Gage and he described alterations which are induced in the circulating blood by starvation and by the subsequent administration of milk protein in the form of sanatogen. The conclusions set forth in the present paper are based on three distinct sets of experiments made with sanatogen, which gave them such marked changes in the blood. General conclusions are as follows: Starvation leads invariably to a rarefaction of the cell body and its processes, as is evidenced by the diminished staining powers of the cell plasms of all cells in the body. The nervous system also suffers during starvation to a much greater extent than ordinary measurements by weight would lead one to suppose. This loss, if stimulation of the nervous system is eliminated, is restricted to the conducting paths, as is proved by both the nerve cells, apart from Nissi's substance, and also the nerve fibers staining much less deeply in starved than in fed animals. That Nissi's substance is diminished, during functional activity Mann has proved previously. Feeding with sodium caseinogenate containing 5 per cent. of sodium glycerophosphate it is possible within two hours to get a definite increase in the nuclear activity even of cells which are not supplied directly by the blood, as, for example, in the cornea and in cartilage. This milk protein further leads to an increased depth of staining of the heart muscle and of nerve fibers, and this deeper staining it is impossible to explain in any other way, except to assume that the amino-acids liberated by the digestion of the caseinogen are actually built up into what Mann has termed the "available" protein.

5. **Toleration of Arsenic by the Human System.**—H. G. A. Harding conducted a series of experiments to ascertain the toleration of arsenic by the human system. H. G. A. Harding records experiments undertaken on himself to test the tolerance of arsenic by the human system. He commenced with 1/30 gr. doses three times a day immediately after food, and

continued for four days without any results beneficial or otherwise. Analysis of an aliquot part of the urine passed, the daily dose of arsenic being 1/20 gr. yielded 1/50 gr. per diem, thus showing 3/100 gr. per diem otherwise disposed of. Doses of 1/15 gr. were taken on an empty stomach three times daily. The result was that the system became irritated and a distinct feeling of discomfort was experienced lasting over two hours; 75 per cent. of this amount appeared in the urine; 1/5 gr. was then taken at a single administration. This also produced irritability and uncomfortable abdominal pains of a more or less severe character. Recourse was now had to the old dosage of 1/15 gr. and after the system became quite normal again the dose was increased to 1/12 gr., then to 1/10 gr., 1/8 gr. and to 1/5 gr. By thus going gradually to 1/5 gr. it was found that the amount was quite well tolerated without any discomfort or marked changes, and, moreover, the average percentage of the drug appearing in the urine was maintained. At this stage, but not before, the urine began to depart from normal. Proceeding still onward the doses were increased to 2/3 gr., 3/4 gr., 5/6 gr., 1 gr. At this point it was felt that the limit was being approached. The next and highest dose reached was 1 1/5 gr., which produced irritability and distinct and lasting discomfort every way it was taken, and all precautions notwithstanding. The drug was now discontinued, but fullness after meals and general derangement were felt for several days. Harding then kept on with the drug, decreasing the amount daily. In one week 1/5 gr. was reached and in less than another week arsenic was dispensed with altogether without any of the symptoms mentioned above.

10. Effects on the Female Generative Organs of Intestinal Stasis. H. Chapple.

**2. Torn Semilunar Cartilages.**—W. Robinson draws attention to the fact that, as there can be a tear without displacement, the name "torn menisci" or "torn semilunar cartilages of the knee joint" should replace that of "dislocation of the semilunar cartilages." After describing the anatomy of the semilunar cartilages in their relation to the knee-joint and the mode of production and nature of torn cartilages Robinson says a certain diagnosis can often be made solely from the history. In nearly every case we learn by inquiry that there has been a severe twisting of the leg in walking, or even turning over in bed. In workingmen there is only one treatment, namely operation.

**3. A Possible Fallacy in the Diagnosis of Internal Derangements of the Kneejoint.**—S. Mort reports three cases in which operation for displaced, loose, or fractured semilunar cartilages revealed little or no change in the interior of the joint, but there were periarticular rheumatoid affections of a spur-like character simulating it. The symptoms were: (1) Pain, swelling, and clicking sensations on movement. (2) A sickening pain and often a sensation of something having given way in the joint. (3) "Locking" of the joint; that is, inability to extend the limb, if the anterior part of the cartilage be torn, or much less often to flex it, if the rent is in the posterior half. (4) A temporary effusion into the joint, traumatic synovitis. (5) One or several recurrences of the above symptoms, especially of "locking" of the joint on slighter but similar accidents, such as slipping off a branch. The site was internal in all cases, the tendon of the sartorius muscle riding upon a distinctly lipped portion of the inner border of the femoral condyle. In the three cases injury was adduced as the supposed cause; incipient rheumatoid arthritis was the real cause, and operation was beneficial in allowing the deformed spur of bone to be burred off though signs of typical rheumatoid change were developed afterward. Mort believes such cases with external joint trouble, and others with typical internal mischief, often referred to internal traumatic damage, to be much more commonly the resultant of rheumatoid diseases than is usually diagnosed. Sometimes they are due to exostoses, in other cases tuberculosis may be a factor. Their importance of their clear recognition, especially in cases of compensation proceedings for injury is obvious.

**5. The Use of Ionic Medication in the Treatment of Certain Venereal Diseases.**—R. Connell reports cases of primary syphilis, secondary syphilitic ulcerations, gummata, soft sores, septic buboes after operation, and gonorrheal rheumatism treated by ionic medication. The best results were obtained in those cases of syphilis in which there was no evidence of a mixed infection. In the Royal Naval Hospital, Plymouth, it has been the practice to give internal antisyphilitic treatment as soon as the diagnosis is confirmed. This consists of grey powder gr. ij thrice daily and to the majority of cases three injections of neosalvarsan are given in addition. It may be, therefore, objected that the results of cases given in this paper were really due to the neosalvarsan or the mercury, rather than to the ionization, but several of the cases mentioned were almost completely healed before the first dose of neosalvarsan was given, and the two most striking cases had no salvarsan at all. The improvement too follows so hard upon the first application of ionization and is at once so marked that to the observer there can be no doubt as to the cause. Also, certain stubborn cases which failed to respond to mercury and salvarsan cleared up rapidly on the application of ionic medication; and before this treatment was tried it was unusual for primary sores to be healed until some time after the three injections of salvarsan had been given. Ten cases of successful treatment by this method are given and the technique is described. Attention, however, is drawn to the fact that this treatment must be regarded as purely local, although Connell suggests that when greater experience of it has been gained by a more extended trial, it will prove to be one of the most rapid methods of healing a superficial syphilitic lesion, whether primary or secondary. Gummata, non-syphilitic lesions, soft sores, and septic buboes are according to the author all amenable to treatment by ionic medication, and in support of the statement cases successfully treated thus are adduced.

**7. Autointoxication and Sub-Infection.**—J. G. Adami describes Sir Arbuthnot Lane's thesis of chronic intestinal stasis and its sequelæ and goes on to criticise the term autointoxication. He thinks that the word should and must be banished from the vocabulary of all self-respecting medical men. Speaking as a pathologist, in the etiology of intestinal stasis, lies his main criticism

of Lane's views. To say, as Lane at least implies, that without intestinal stasis there would be no generalization of tuberculosis, is, it may be urged to ride one's horse to death. Adami strongly opposes Lane's teaching that the colon is merely a "common sink" and argues that encouraged by Lane's brilliant advocacy, encouraged to regard the colon as of no account, the immature surgeons of two continents will inaugurate an era of short circuiting, performing this or the yet graver colectomy for all sorts and conditions of diseases of men, women, and children on the smallest possible pretext. Adami is of the opinion that subinfection will explain all of the consequences attributed by Lane to intestinal stasis and autointoxication. His conclusions are as follows: (1) It is more rational to regard the evil effects of intestinal stasis as, in the main, a result of conditions favoring subinfection and low forms of infection than as a result of chronic intoxication. (2) The term "gastrointestinal autointoxication" is pernicious and not to be employed by any self-respecting member of our profession, save for so limited a set of conditions that for ordinary purposes it may safely be expunged from the medical dictionary. (3) While the symptoms and diseases enumerated by Sir Arbuthnot Lane may follow intestinal stasis, at least, a large proportion of these may originate independently of such stasis. (4) Before recommending the operation of short circuiting, it is necessary, therefore, to make the fullest studies, so as to discover, if possible, the nature of the organism responsible for the disturbance and its probable seats of entry. (5) A discovery of the cause of the symptoms is calculated to suggest the appropriate means of treatment by means other than short circuiting. Only when these have been tried and found wanting is removal or short circuiting of the colon justifiable.

8. **Anatomy and Treatment.**—S. S. Pringle in an anatomical consideration of intestinal stasis says to his mind there are two distinct factors in its production: (1) Ptosis of some part of the gastrointestinal tract and (2) kinking and stenosis of the bowel by bands and membranes; in other words, we may speak of "stasis of gravity" and "stasis of obstruction." There are midline ptosis and right-sided ptosis. Pringle describes at length the various bands and membranes and points out that the treatment of chronic stasis is a subject of lively controversy. On the one hand, Lane advises ileocolectomy or complete colectomy in all severe cases, while, on the other hand, orthopedists as Goldthwait claim to be able to cure even most advanced cases by belts, exercises, etc. Pringle after treating many of these cases considers we may divide the treatment into: (1) Prophylactic; (2) medical; (3) local operative; (4) radical operative. Prophylactic treatment consists of suitable exercises, the acquiring of a regular habit of emptying the bowels and the avoidance of the routine use of aperients. If there is any costiveness, it should be combated early by the regulation of the diet, belts, exercise, and the use of liquid paraffin. The latter can be taken in doses of 1 to 4 drams three times a day flavored with one of the essential oils, as cinnamon or peppermint. A few patients find it impossible to take it in this form and then one or other of the proprietary preparations may be ordered. The author enters into the technique of many of the local operations and then describes the two radical operations. With regard to colectomy Pringle says patients after complete colectomy make good recoveries, put on flesh, and gain better health than they have experienced for years; in fact, they derive the greatest benefit from the removal of their great bowel which has lost its original function and degenerated into a cesspool, as tersely expressed by Lane.

9. **Etiology and Treatment.**—H. M. W. Gray thinks that it is curious how many surgeons are still skeptical about the presence of membranes which interfere with the full action of the bowel. All one can say is, that although their presence may not be "well recognized" they are very easily recognizable. As to the etiology of these membranes there is as yet no unanimity. There is a tendency for two schools to be set up. One, with Lane at its head, believes that these membranes are the result of the stasis. The other school believes that they are developmental in origin. Gray could never bring himself to accept Lane's theory as to the origin of the membranes, and after much consideration of the matter and study of the conditions found at operations he came to the conclusion that the membranes were congenital and gave voice to his opinions two years ago. As frequently happens, workers in another country, Connell and Flint in America were on the same track about the same time. Still less can Gray credit the theory that they are due to long continued inflammation. If these are studied, the fact will be appreciated that they are all due to an excess of developmental fusion or to a deficiency of developmental absorption. These may be present in well marked form without producing constipation. The stasis is caused by the manner in which these bands are attached to the bowel or its mesocolon. If the membrane is short and causes angulation of the bowel, sooner or later it will be the cause of stasis proximal to the angulation. The great indication for any surgical interference is the presence of dilatation and hypertrophy, be this in stomach, gall-bladder, small intestine, or colon. When admissible Gray prefers division of the membranes to the operation of colectomy, because it is a less formidable and in suitable cases an equally efficacious procedure. He thinks that colectomy should be given the preference when there is marked ptosis of the ascending or transverse colon, or, when accompanying an acute angulation. The results of successful operative procedures are very striking. The patients often veritably seem to renew their youth. They sleep better, eat better, and feel better. They are desirous of and capable of leading more active lives; that is, they lose their mental and physical lassitude. What seems to give most delight and satisfaction is the natural, regular, and free motions of the bowels. Proper treatment will have an effect on the peace and prosperity of the nation, for is not Sir Arbuthnot Lane reported to have said recently that "he can understand a man preferring to live with a drunken woman rather than a toxic one. A drunken person is occasionally merry, but a toxic one never?"

10. **Effects of Chronic Intestinal Stasis on the Female Generative Organs.**—H. Chapple referring to the band now generally known as Lane's kink and the argument that bands of this nature are of congenital origin, said that with the object of inquiring into this point he had opened and carefully examined at Guy's Hospital thirty-one fetuses. Their ages varied from four to nine months, but in no case had he been able to find anything that might be considered a true Lane's kink. Chapple mentioned that he had recently received confirmatory evidence in this direction in the form of a beautiful series of pictures from the clinic of Dr. Bainbridge of New York. Chapple pointed out how gravely intestinal stasis affected the generative organs of women and that operative measures for its relief almost invariably had a remarkably favorable effect on these organs. Especially was this so in the degenerative changes which accompanied or followed intestinal

stasis. Attention was drawn to the fact that opinions on the subject of intestinal stasis of those members of the medical profession whose notice had been called to it had undergone a very rapid change and that nothing could better illustrate this change than the address in surgery delivered before the annual meeting of the British Medical Association at Brighton in 1913. This surgeon referred to Lane's disease as a clinical entity.

*January* 6, 1914.

**Acute Fetid Diphtheritic Bronchitis.**—Beyer reports the following female, aged 31. As a child had had scarlet fever and articular rheumatism, with repeated attacks of angina. At 23 went through pleuropneumonia. Her present illness began with chills and fever. First diagnosis angina, to which she was subject, followed by pleuritic symptoms. In a few days acute symptoms had passed, but she was left with a severe cough which ended in vomiting. Angina still in evidence, and cervical lymph nodes swollen. The woman was unusually strong and robust and her constitution suffered but little, the organs affected comprising only the throat, including the larynx, and perhaps the bronchi. Patient coughed up a pint of purulent expectoration, extremely foul smelling. Bacteriological tests showed the Loeffler bacillus in pure culture. Serum at once injected into a vein. There was a distinct improvement after injection of 2000 units. After patient had apparently recovered from the disease, she was kept under treatment of the larynx, and also until the disappearance of the germs from the sputa. The author dwells on the presence of a psychic factor in activating latent bacilli. The author has seen cases follow dreams, fright, operation on tonsils, also of course exposure to cold and wet. In the author's case the infection traveled directly from tonsil to bronchus, indicating an absence of natural antitoxin; her symptoms promptly disappeared after one injection of serum.

**Clinical Studies with Abderhalden's Dialysis Procedure.**—Oeller and Stephan, working in von Strüpell's clinic, remind the reader that thus far this test has been applied to extensive domains, as gynecology, obstetrics, psychiatry, internal medicine, bacteriology and malignancy. They review the validity of these tests in the departments just enumerated. Thus in obstetrics the test is trustworthy save for the fact that it is positive in non-pregnant women in a certain number of cases. The test has also met with the same degree of success in psychiatry. In gynecology, despite some surprising successes, it is impossible to lay down any laws from the reports which have come in. In regard to malignant growths the author, after a long review of testimony, decides that the method here has thus far been a failure, but other substitute procedures may bring about better results. The article will be continued.

### Deutsche medizinische Wochenschrift.

*January* 8, 1914.

**Cardiac Disturbances after Accidents.**—Paul Horn sums up a very long study of this subject as follows: Cardiac disease may result from psychic or mechanical causes. Psychical causation may be primitive or secondary. When due to mechanical causes we may see functional disorders alone, function disorders becoming organic, and cases organic from the beginning. When due to fright, primary psychogenic cardiac disorders are usually accompanied by vascular anomalies or other phenomena of a vegetative nervous system. Secondary cardiac disturbances of a functional character are comprised in the picture of neurasthenia, the subject of a damage process. The cardiac disorder is not a condition *per se*. In other cases we see arteriosclerotic changes as a result of the same type of neurasthenia. Arteriosclerosis has occasionally followed a blow on the head. The prognosis of functional cardiac disorders after accident is as in the case of most accident neuroses, favorable, supposing the indemnity claims are promptly and definitely settled by a single examination. In a damage suit, symptoms dwindle away more slowly. An expectant behavior is to be recommended in the damage suits following breast contusions which are followed by apparently functional cardiac disorders. Organic injury to the heart after mechanical injury appears at first as if purely functional, but gradually or abruptly becomes organic, leading to notable alterations in the heart and circulatory disorders.

**Causation of Contracted Kidneys.**—Enderlen lays most stress on cooling of the surface in the genesis of this affection. Some years ago an investigator dipped a dog's paws in cold water, and later demonstrated on microscopic slides the occurrence of acute nephritis. The ill effects of wetting the feet in causing various catarrhal affections is well known. The association of nephritis with sweating feet has usually meant that the former is provocative of the latter, but the author contends that these furnish a special predisposition to chilling. Leaving out of question other known causal factors, sweating feet are present in all where other factors were absent. As hypendrosis may be familial affection, the author was not surprised to find that nephritis was later associated in the same members of the family. Chronic cold and wet in other words represent a summation of insidious injury to the kidneys. The latter may not be strong enough to cause actual nephritis in a given case. Thus far the author has not explained the connection between acute nephritis and contracting kidney. He appears to believe, however, that the same rational applies to both primary and secondary chronic contracting kidneys. The acute phase, often overlooked, may be styled acute nephritis from exposure. The author thinks much might be done in the way of prophylaxis by using formalin lotion on the feet which prevents the saturation of the stockings by the perspiration.

**Epidemiology of Rhinoscleroma.**—Does this affection originate in separate foci or is there an epidemiology which can trace the disease from one focus to others? Friedrich mentions a focus in East Prussia in where were to be found 28 cases, chiefly familial. The disease is known to be moving slowly from East to West, but this emigration cannot be followed out. The author has seen one case in West Prussia, an isolated one. After much effort this case was traced directly to the focus in East Prussia.

**The Absence of the Oculo-Cardiac Reflex in Tabes.**—M. Loeper and A. Mougeot describe this reflex as follows: Compression of the eyeball is followed in two or three seconds by a diminution of the rate of the heart beat to the extent of eight pulsations per minute. This reflex is abolished in tabes. The absence of this reflex has the same significance as the Argyll-Robertson pupil.—*Le Progrès Médical.*

**Senile Osteomalacia.**—S. Bonnamour and A. Badolle point out that the first symptom of this condition consists in the pains referred to the spine, the sides, and the sterum. Later the bony deformities develop, chiefly in the spine, with consequent shortening of the stature. The *x*-rays reveal a loss of the normal opacity of the bones. A special cardiac symptom noted is the occurrence of paroxysmal attacks of dyspnea.—*Gazette des Hôpitaux.*

# Insurance Medicine.

## SUGGESTIONS TO THE MEDICAL EXAMINER.

BY THE INSURANCE EDITOR.

### GOITER.

CONTINUED research for the purpose of determining the function of the thyroid gland has encountered difficulties and, although our knowledge is more accurate than formerly, there are various conflicting theories in regard to the matter. We do know that the thyroid is essential to life and that death ensues when it is wholly removed. Any disease of the gland is, therefore, an important matter and it becomes the duty of the medical examiner to make an inspection of the throat of every applicant, as small goiters frequently escape discovery. Simple goiter was formerly regarded by many as a disease largely confined to continental Europe, but it is now recognized that the disorder is fairly common in many localities. In the United States and Canada, it is frequently found in the region of the Great Lakes and in scattered centers.

In 1902 one company made an investigation of the subject of goiter through its medical representative in Austria, the data in this country at that time being insufficient, and the following directions were formulated for use by the medical examiners in collecting information. They should be carefully observed in every case of thyroid enlargement:

1. Congenital or acquired?
2. Size of goiter?
3. Has it increased in size during the past five years?
4. Is the growth substernal?
5. Is it due to simple hyperplasia or hypertrophy, or is it cystic or degenerating?
6. Have there been any signs of disturbance of the nervous system or of pressure?
7. Any exophthalmos?
8. Is the applicant's place of residence free from conditions which predispose to tuberculosis?

Reviewing these directions, it may be added that an applicant with a congenital growth is uninsurable. The tumor should be small enough to remove the probability of pressure, and if there has been any increase in size in the last five years the risk should be declined. Pressure upon important parts depends more on position than size and, for this reason, a careful examination should be made to ascertain if any portion of the goiter is substernal, a condition which should cause rejection. The cystic or degenerating goiters are apt to lead to a fatal termination through hemorrhage, necrosis, or septic poisoning. Large cysts are easily recognized, especially if superficial, but small ones are almost impossible to detect unless extraordinary care is observed in the examination. When there is a history of disturbance of the nerve centers or of exophthalmos the applicant should be summarily rejected, for another and more serious condition is encountered under such circumstances in the form of Graves' or Basedow's disease. The relation between simple goiter and Graves' disease is not understood, but it is always highly important to search for evidence of Graves' in every case of goiter. All forms of goiter may be involved with Graves' disease for the reason that it is possible for thyroids, already diseased, to more readily undergo other changes. On the other hand, cases of Graves' disease are met without thyroid enlargement, and at other times without exophthalmos. It is difficult to explain cases in which a previously healthy gland undergoes the degeneration peculiar to Graves' disease. The disturbances in Graves' disease seem to be caused by a morbid product which acts on the heart, tissues, central nervous system, and skin without much or any relation to hypertrophy of the thyroid.

The Austrian corespondent further advised that applicants should be accepted only when between the ages of 25 and 50 upon endowment plans which would terminate not later than age 65, and that only 15 year endowments should be issued to women at any age. This opinion was based upon conditions existing in continental Europe, and should still be regarded as correct when applied to risks assumed in that part of the world. Later experience and observation in this country have led to the conclusion, however, that the rulings may be modified in dealing with individuals living in the United States and Canada, as the goiters found here are generally considerably smaller and pursue a much less eventful course than those met with in Europe, cretinism and other complications being comparatively rare. This difference may be easily explained by the better conditions under which our own people live, and possibly to less active exciting agencies. The distinction in regard to sex may, also, be largely ignored, for while it is probably true that goiter is more common among women on account of frequent congestion and hyperemia excited by the sexual functions, the facts remain that women in this country have lighter burdens, that they are better cared for during menstruation and pregnancy, and that their special ailments receive more attention. Furthermore, they have hygienic homes and surroundings, and nourishing food. Another point applying to both sexes is that the value of an early resort for preventive as well as curative treatment is more fully understood by the lower middle classes in this country than in Europe, and any awakened activity of the growth will inspire an early search for medical assistance.

If the report of the examiner is satisfactory, it may now be considered good practice to adhere to the following plan in the process of selection at the home office:

1. No distinction should be made between men and women.
2. The youngest age at which applicants with goiter should be accepted may be set at 20. This gives an ample opportunity to determine whether the goiter is progressing or liable to become active.
3. A policy on the 15 or 20 year endowment plan may be granted according to the age of the applicant. The contract should terminate at an age not later than 65 in the great majority of cases.
4. In a few carefully selected cases a policy on the life plan may be granted. The applicant must have reached the age of about 30; the goiter should be decidedly small; the history of the growth should show it has existed for many years without enlarging or showing any signs of activity; no medical or surgical treatment has been resorted to; the applicant must be intelligent enough to realize the importance of treatment in the event of any signs of activity; the surroundings must be unquestionably hygienic; the occupation should be healthful; the personal history should be without blemish, and there should be no taint in the family history; and the financial means should be sufficient to allow a ready recourse to medical aid.

## Book Reviews.

A Textbook of Histology. By Frederick R. Bailey, A.M., M.D. Fourth Revised Edition. Profusely Illustrated. Cloth; 644 pages; price $3.50 net. New York: William Wood & Company, 1913.

This book was written for use in classroom teaching in connection with laboratory work by the student and is admirably adapted for that purpose. With this idea in mind, the author has made the text as concise as possible, yet has given entirely adequate descriptions of the essentials. The work is divided into four parts: (1) Histological Technique, (2) The Cell, (3) The Tissues, and (4) The Organs. In the first section the composition and preparation of staining fluids, methods of preparing, mounting and staining specimens are given, including both the simple and many of the more complex procedures, such as the Golgi, Cajal, and Weigert-Pal methods of staining nerve tissues. References are given at the end of the section for further study of technique, as is found to be the custom throughout the book. In the section on the cell, the fibrillar, granular, and foam or emulsion theories of protoplasmic structure are briefly outlined, the question as to the ultimate structure of protoplasm still remaining unanswered. This is followed by a description of the vital properties of cells, cell division, fertilization of the ovum, and technique. In the third section, after enumerating the special tissue derivations from each of the three primary layers of the blastoderm (ento-, meso-, and ectoderm), chapters are devoted to epithelium (including meso- and endothelium), the connective tissues (including cartilage and bone), the blood, muscle tissue, and nerve tissue. The remainder of the text, about 450 pages, deals with the special organs of the body. In this division the portion devoted to the nervous system is especially voluminous, and furnishes a remarkably lucid exposition of this most complex portion of the human organism. Much anatomy has been incorporated in this section and adds materially to the teaching value of this part of the book. An unusually complete index deserves special mention. The book is profusely illustrated, valuable for reference, as well as for classroom use, and may be conscientiously commended by the reviewer.

The Dietetic Treatment of Diabetes. By B. D. Basu, Major, I.M.S. (Retired). Fourth Edition. The Panini Office. Bhuvaneshvari Ashram. Bahadurganj, Allahabad, 1913.

The author considers diabetes in most cases as a manifestation of alimentary "toxicæmia" and upon that consideration bases much of the treatment which he advises. The diets given are the conventional ones except where they take advantage of the natural products of India, such as the cocoanut.

International Clinics, a Quarterly of Illustrated Clinical Lectures on Treatment, Medicine, Surgery, etc. Edited by Henry W. Cattell, A.M., M.D. Vol. IV, Twenty-third Series. Price $2.00. Philadelphia and London: J. B. Lippincott Company.

This issue of the International Clinics contains eighteen articles on diagnosis, medicine, neurology, surgery, and eugenics. The most important article is one on traumatic lipemia and fatty embolism by Alfred Scott Warthin. Others of interest are Azurphile microorganisms by F. Proescher and factors in the clinical physiology of the heart by Henry Sewall. The number is an exceedingly good one, rather above the general grade of excellence exhibited by this publication.

Hair. Its Nature, Growth, and Most Common Affections, with Hygienic Rules for Its Preservation. By Richard W. Müller, M.D. Price $1.50 net. New York: William R. Jenkins Company, 1913.

In this interesting book the writer gives the results of years of research at the clinics, universities, and hospitals of Paris, London, Vienna, and Berlin. In the last twenty years the diseases of the scalp and hair have been most thoroughly studied by various schools. Notwithstanding the fact that these disorders are for the most part cosmetic diseases, such men as Sabouraud of France and Unna of Germany have been leaders in these investigations. As a result, the subject has been invested with a new dignity and interest. The author has been permitted to use in this volume some of Sabouraud's fine plates made for his own work on diseases of the hair, which is as yet unfinished. Ignorance of the nature, characteristics, developments, and diseases of the hair is almost universal. So are various affections of the hair. With these facts in mind, the author discusses the nature and growth of hair, the different forms of baldness; with their causes; superfluous hair and its removal; knotted hair, split hair, parasitical and fungoid diseases of the hair, and hygiene of the hair. Extremely interesting and valuable is the last chapter—on food in general and especially for the growth of hair. To emphasize the great importance of proper food and especially the proper manner of eating it, the latest statistics of Dr. Lucien Jacques, of the Saint-Antoine Hospital of Paris, are given here. Seventy-one patients who had consulted Dr. Jacques for great loss of hair were found to be suffering from gastrointestinal disorders. A series of prescriptions are appended for convenient reference and the book is completed by an excellent index. This handy little volume is sure to prove of value to the general practitioner as well as to the laity.

Modern Problems of Biology. Lecture Delivered at the University of Jena, December, 1912. By Charles Sedgwick Minot, LL.D., Yale, Toronto, and St. Andrews; D.Sc., Oxford; Director of the Anatomical Laboratories, Harvard Medical School; Exchange Professor at the Universities of Berlin and Jena, 1912-13. With 53 illustrations; price $1.25 net. Philadelphia: P. Blakiston's Son & Co., 1913.

At the request of the Grand Duke of Saxe-Weimar, the Rector Magnificentissimus of the University of Jena, Dr. Minot, at the time Exchange Professor at Berlin University, delivered a course of six lectures at the former university, the subject chosen being modern problems in biology. These lectures are here published in book form. The researches referred to in the lectures were mainly American, and this was done because the author was the American Exchange Professor and partly because he was informed that his audience in Jena would like to hear especially about American discoveries. The result has been that Professor Minot has presented the modern problems of biology in lucid and attractive form which must give a thrill of pride to Americans. That no more able exponent of American researches in biology could have been found than the Harvard professor, himself among the most eminent of all American investigators in this field of science, goes without saying.

The Practical Medicine Series. Comprising ten volumes on the Year's Progress in Medicine and Surgery, under the general editorial charge of Charles L. Mix, A.M., M.D., Professor of Physical Diagnosis in the Northwestern University Medical School. Volume VII—Obstetrics—Edited by Joseph B. DeLee, A.M., M.D., Professor of Obstetrics, Northwestern University Medical School, with the collaboration of Herbert M. Stowe, M.D. Series 1913—Price $1.35. Chicago: The Year Book Publishers.

Although there has been no particular advance in obstetrics during the past year, this book is valuable, as it contains synopses of many interesting and instructive cases which were reported in the literature of the year. This volume should prove of particular service to the physician in general practice.

Die Malaria nach den neuesten Forschungen. Von Prof. Dr. Angelo Celli, Direktor des Hygienischen Institutes der Universität Rom. Zwete Deutsche Auflage nach der verten neubearbeiteten Italienischen Übersetylung. Von Anna Fraentzel Celli. Price, 16 Marks. Berlin: Urban & Schwarzenberg; New York: Rebman Company, 1913.

Professor Celli has revised his work which appeared in 1900, as he believes the experience gained in the last decade in Italy should be extended to the other parts of the world in a language common to the world of savants. In view of our own work in the Southern States, in Panama and in the Philippines, the hopeful conclusion of the author that colonies can be grounded in the most dangerous malarial tropical regions from one day to the next is enlightening. Celli believes that one must at all events keep the man exposed to malaria in good physical condition, and if he falls sick he must be treated energetically and quickly so that he can continue his hydraulic and agrarian labors. The therapy is quinine, both as preventive and cure. The other antianophelin measures are practically too complicated to be used in the country. Professor Celli warns both authorities and physicians against the advocacy of any exclusive theory and advises them to proceed according to "unum facere et alterum non omittere."

# Society Reports.

## MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

*Stated Meeting, Held December 22, 1913.*

THE PRESIDENT, DR. BROOKS H. WELLS, IN THE CHAIR.

**Amebic Dysentery with Special Reference to Its Treatment with Emetine.**—DR. FRANK C. YEOMANS presented this communication. He first reviewed the history of the use of epecac in dysentery from the time of its introduction into Europe from Brazil by Piso in 1658. While the value of this drug in certain forms of dysentery had been recognized its use had been limited because of the impossibility of administering therapeutic doses without causing distressing nausea and vomiting. Following the demonstration of Rogers, in 1907, that ipecac would rapidly cure an amebic hepatitis in the presuppurative stage and so prevent the formation of liver abcesses, the administration of large doses of the drug returned to favor and good results were reported by Simon of New Orleans in 1909, and by Dock, Brem, and Zeiler in Panama. Emetine was recognized as the nauseating constituent of the epecac and also as the principle that controlled amebic dysentery. One grain of emetine was equal to about ninety grains of powdered Brazilian epecac root. Dr. Yeomans reviewed the work of Rogers in India, J. Preston Maxwell in China, and Baermann and Heinemann in Sumatra. The latter, as a result of their experiments concluded that 250 mgs. was the maximum dose for a body weight of 60 kilos and that 200 mgs. was fully as sufficient. With this dose the kidneys escaped damage. They had a mortality of 32 per cent. in their series of 22 cases, but this was no reflection on the value of the drug; on the contrary more than one-half the patients were cured of severe chronic or acute fulminating forms of the disease, the majority of which, because of profound toxemia, were foredoomed to failure by any method of treatment. Fortunately these severe types of amebic infection rarely occurred in the temperate zones. In one of their series of cases in which emetine given subcutaneously had failed, a cure was affected by a single intravenous injection. It was also worthy of note that necropsy on the seven fatal cases showed the ulcers healed or healing in every instance and stained sections through the ulcers were practically free of amobæ. Dr. Yeomans said his personal experience with emetine comprised seven cases, three of which were treated at the protocological clinic at the Polyclinic Hospital. Six of these cases were males and one a female. All were adults except one, a boy of twelve years. Three had contracted the disease in or near New York, and one each in Germany, Cuba, the Philippines, and India. The disease had varied in duration before treatment with emetine was instituted from six months to 14 years. Entamebæ histolyticæ were demonstrated in every patient. Other forms of treatment had been employed in all cases with temporary relief only. The amount of emetine hydrochloride injected varied from two and one-half to 14 grains, with an average of three and one-half grains. Five patients were cured clinically and two greatly improved. The term clinical or apparent cure was used advisedly, for one could not pronounce a patient really cured of this intractable disease until a long period of time had lapsed without recurrence. It was not less than marvelous to watch through the proctoscope the healing of ulcers while the emetine was being administered. It would convince the veriest skeptic of the specific action of emetine in amebiosis and was comparable only to the disappearance of syphilides after the use of salvarsan. The non-recognition of amebic dysentery was due to failure to make proper examinations. Every patient who did not respond to a few days of ordinary treatment should be proctoscoped, as the proctoscopic picture in amebic dysentery, if not pathognomonic, was certainly very characteristic. If ulcers were found the discharge should be transferred directly from their surface to the warm stage of a microscopic field and examined immediately. The only absolutely pathognomonic sign of amebic dysentery was finding the pathogenic amebæ. Failing the equipment to make a proper examination, Rogers had suggested the therapeutic test of two or three doses of emetine given by needle. If decided improvement did not result they were probably not dealing with a case of amebic dysentery, for emetine had no effect on the bacillary or other forms of disease. Emetine as used in the form of a soluble salt, emetine hydrochloride, which came in tablets of various strengths and also in hermetically sealed ampoules, containing the salt dissolved in sterile solution. The average dose was one-half grain of emetine hydrochloride dissolved in ten to fifteen minims of normal saline solution and injected subcutaneously in the outer part of the arm over the deltoid. This dose was administered daily for three to seven days, depending upon the return of the stools to the normal, the absence of amebæ and the healing of the ulcers as shown by the proctoscope. When the signs and symptoms of the patient indicated a clinical cure the emetine should be discontinued, for an excess of this drug in its excretion through the bowel would cause irritation. Dr. Yeomans said he had had no experience with intravenous injections and believed they were seldom, if ever, indicated in the type of cases met with in this latitude. During the treatment the patient ate a non-irritating diet and rested as much as possible, though not necessarily confined to bed. The stools should be disinfected as in typhoid fever. The essayist concluded that in emetine they possessed a specific for amebic dysentery in the same sense that quinine was a specific for malaria and salvarsan for syphilis. Used at the outset of the disease cure should be prompt and permanent in all cases. After weeks, months, or years latent amebæ might reappear, hence amebic patients should be kept under prolonged observation and on the first signs of recurrence a course of emetine should be given.

DR. JEROME M. LYNCH said that he had nothing to add except to say that the diagnosis of amebic dysentery was comparatively simple after one had once observed a few cases. The infectious character of the disease was illustrated in that at one time he had traced ten cases to a little grocery store in lower New York, where Armenians were accustomed to congregate in the evening. He believed that those men were infected from the groceries in that store. He had met with a case to-day in an Armenian and he meant to look up his history and to see if he could trace the infection. In amebic dysentery there were three stages: (1) The catarrhal, (2) the necrotic, and (3) the ulcerative. The ulcers were typical in that the edges sloped in to a base one-half the circumference of the outlet. Up to the time that Rogers published his paper they had used surgery in amebic dysentery and had obtained good results because they kept the opening patent for a year and a half. One should remember that if the disease had existed for a long time a mixed infection was present and not a pure amebic dysentery. The question then arose as to whether such cases could be influenced by emetine. In regard to operative measures Dr. Lynch said he preferred an ileostomy to an appendicostomy. With the appendicostomy one had fecal matter passing over the ulcers and it was difficult to effect a cure. Ileostomy was far superior. Many had the idea that an ileocostal opening was inconvenient, but after about six weeks the ileum took up the function of the colon and formed movements were passed from the ileum.

DR. JULIUS W. WEINSTEIN said that he had one case of amebic dysentery in a man 38 years of age who had contracted the disease in the Brazilian gold fields. The dysentery had been present fourteen months when he first began to treat the patient. He had previously been treated in several hospitals, but without much improvement. His history and physical examination were typical of amebic dysentery. Several ulcers were present and the ameba were found in the discharge from these. He had administered emetine hydrochloride hynodermatically beginning with small doses and increasing them until he gave two-thirds of a grain. There were no ill effects and the two-thirds of a grain were equivalent to sixty grains of inecac. From the first administration all symptoms disappeared and in a short time the stools became natural. At the end of three weeks treatment was discontinued against his advice. The patient returned later with a recurrence. There were many species of amebas, but it was only the entameba histolytica that caused this form of dysentery. In any patient in whom amebic dysentery was suspected a proctological examination should be made, and if several ulcers were present the secretion from these should be taken and examined, and if the amebæ were present one could be sure of the diagnosis.

**Fracture of the Skull: The Roentgen Ray as an Aid in Its Diagnosis.**—Dr. W. H. LUCKETT and Dr. W. H. STEWART presented this communication. Dr. Luckett first described the anatomy of the skull, calling attention to the weak points which were particularly susceptible to injury. These were the centers of the orbital plates of the frontal bones, the middle cerebral fossa, the center of the squamous portion of the temporal bone, and the center of the inferior occipital fossæ. These points seemed to have a direct bearing on the location of fractures, particularly of the bursting linear fractures extending into or originating in the base from blows on the thicker expanse of bone forming the vault, or blows on the point of the jaw, or from violence transmitted upward from the spine, as falls on the buttocks. The essayists pointed out reasons why fractures of the skull had a tendency to replace and maintain themselves, and that for this reason a fracture of the skull in itself was of secondary importance, the vital consideration being the amount of injury to blood vessels, intracranial nerves, dura, and brain substance, and the opening up of possible avenues of infection, meningitis, cerebritis, encephalitis, abscess, epilepsy, softening, secondary traumatic insanity, post-operative psychoses, and post-operative neuroses. As a clue to the location of the serious lesion the fracture was of the utmost importance. The writers showed that in view of the findings with the *x*-ray the statistics as to the frequency of fractures of the skull were altogether too low. Fracture of the skull resulted in many instances from apparently trivial causes and the *x*-ray frequently revealed the presence of a fracture where there were no symptoms suggestive of one. The writers stated that they had no hesitancy in saying that the majority of fractures of the skull were not diagnosed as such and remained undiscovered. For these reasons they emphasized the aid that could be rendered in discovering and locating these fractures by means of the Roentgen ray. In a hurried review of the English literature on fractures of the skull they had failed to find the *x-ray* mentioned as a means of diagnosis. Hitherto for every hematoma an exploratory operation had been advised, thus compounding a simple fracture when the *x*-ray would very much more easily aid one. They were all conversant with the number of cases in which the fracture with a lacerated bleeding artery was remote from the point of injury. The frequency with which fractures of the skull were mistaken for various other conditions, especially coma, called for any method which would make a rapid and positive diagnosis. There were a number of cases of fracture of the skull in which diagnosis could be made only by the *x*-ray. This referred to those cases which gave no symptoms, either objective or subjective, only a history of a fall. In the Harlem Hospital every patient who received a blow on the skull, or point of the lower jaw, either directly or from a fall, was considered as suffering from a fractured skull unless proven otherwise. The signing of a release holding the hospital blameless was always required when such a patient desired to leave. The elasticity of the bones was largely accountable for the rarity of basilar involvement in children; this was in marked contrast to this injury in adults where authorities claimed 80 per cent. of linear fractures of the vault extended into the base. The frequency of a serious fracture in small injuries of the head in children and the apparent insignificance of such fractures had been observed. The skulls of children fractured easily without injury to the brain or blood vessels. When there was some injury to the vital tissues the extensive nature of the fracture relieved the tension; in other words, the skull decompressed itself. Just why the radiographing of the skull for a possible fracture like radiographing any other bone for diagnostic purposes had been so generally neglected, practically ignored, was one of those peculiar anomalies that crept into the routine work of medical practice.

Dr. W. H. STEWART prefaced his lantern slide demonstration of radiographic work on fractures of the skull by stating that these patients were often in a comatose or irritable condition and that a great deal of patience and perseverance was required in handling them. It must be constantly borne in mind that the minimum amount of disturbance and movement was the rule. The head must be absolutely fixed and all respiratory movement overcome. If objective symptoms were present they were a clue to the site of the fracture and attention was naturally directed toward that region; this must not mislead one, however, for every case should have the frontal, parietotemporal and occipital regions radiographed. In the examination one should endeavor to show on the radiograph as much of the vertical plate of the frontal bone as possible. This was best obtained by placing the patient flat on the abdomen, with the head, face down, resting on the inclined plane at an angle of twenty-five degrees. A small cone having an outlet of about five inches was used; the vertical axis of this cone represented the central ray and should be centered on the glabella and directed straight down. A tube was used of rather high vacuum, which would take 45 to 50 milliamperes. An exposure of five seconds was given. Frequently the patient's condition would not permit of his being placed in this position and then the procedure was reversed. In radiographing the radioparietal region one should show that portion of the skull lying between the sagittal suture above, the coronal suture anteriorly, the lambdoid suture posteriorly and including the entire temporal bone. Both sides of the head must be examined. For this region a cone having an outlet of seven inches was used. The same conditions governed the tube as in examining the frontal region. The occipital was the most difficult of the three regions and was best examined by having the patient lie on his back, the head resting on the raised platform and the chin sharply flexed. This brought the occiput flat on the plate. In this region a cone with an outlet of four inches was used, the vertical axis being centered on the foramen magnum. The normal radiating lines of the grooves in the inner table of the skull, accommodating the meningeal blood vessels might be mistaken for fractures of the skull. Fractures usually showed in the radiograph as light, sharply cut lines of varying width, depending on the amount of separation. The fracture lines were usually at direct variance with the shadow lines of the meningeal grooves. Dr. Stewart then showed illustrations of fractures in the different regions of the skull. Among the most interesting cases shown was that of a man who was admitted to the hospital with a small punctuate wound over the right supraorbital ridge. In the radiograph the ventricle was distinctly outlined. Decompression was performed, but the patient succumbed later, and, believing the appearance of the ventricle was caused by its distention by air that had entered through the wound, the brain was opened under water and it was definitely proved that air or gas escaped. Another case was shown of a boy who was admitted to the hospital for a fractured femur; several days later it was accidentally discovered by the nurse that he had a fracture beginning high up in the occipital bone over the superior longitudinal sinus, extending downward to the right, passing over the right lateral sinus and ending in the mastoid portion of the temporal bone. A fork extended downward parallel and to the right of the occipital sinus, terminating in the foramen magnum.

Dr. WILLIAM P. HEALY said that this was a subject that was of great interest even if one were not a surgeon or interested in the surgical service of a large hospital. The work described was a decided step forward in the diagnosis of fractures of the skull. Fractures of the skull had been divided into those of the vault and those of the base, and the textbooks had asked them to depend on sight and touch in making a diagnosis. Some injuries to the vault could be seen, but when there was a hematoma one had to cut down and find out what was wrong. He was sure this was the method still used by most surgeons. It certainly was unfortunate to convert a simple linear fracture into a compound fracture, and this was no longer necessary in a properly equipped and manned hospital. In many hospitals the *x*-ray expert was only present a half a day, and this was a difficulty in the practical management of these cases. There could be no question as to the great value of this method in the diagnosis of fractures of the skull, but whether it would be of any aid in the treatment was still a matter of conjecture. The *x*-ray examination of all cases suspected of having a fractured skull was undoubtedly very valuable in the keeping of records, as it could be definitely stated that a case had or had not a fracture. The equipment for making these examinations should be attached to all hospitals and the examination should be made in every case giving a history of a fall, or even of transient unconsciousness.

Dr. OTTO SCHULTZE said that Dr. Stewart was to be congratulated for his excellent showing of Roentgen

ray pictures, but that they did not cover everything. Bursting fractures did not decompress themselves. If hemorrhage was correctly diagnosed one could learn almost as much from it as from the *x*-ray picture. It was not enough to know the line of fracture; one must know whether he was dealing with an epidural clot. When there was a lucid period followed by a gradual sinking into coma, it was probable that an epidural clot was present. One should try to map out this clot and the spinal fluid should be examined for blood; all these things taken together could be relied upon, but if one depended upon the *x*-ray alone he would be led into error. An important point was that the brain might burst at the convexity opposite that at which the injury was received. One statement was made that should be corrected and that was that fractures decompressed themselves. Where there was a comminuted fracture the handle of the lever was broken and decompression did not take place of itself. Again, it should be remembered that the brain might be lacerated and yet there be no fracture of the skull.

Dr. LOUIS J. LADINSKI said that if any one thought that in the Harlem Hospital the diagnosis of fractures of the skull was limited to the *x*-ray examination alone he was very much mistaken. Often even if there was a fracture of the skull there was little damage to the cranial contents. Frequently he was not shown the *x*-ray plate until after he had made an examination; in one case recently he had asked for the *x*-ray plate and was told that they did not want him to see it until after he had made the examination, as they wanted his independent opinion. It was not always easy to make a diagnosis from the *x*-ray picture and sometimes a fracture might exist without being observed in the *x*-ray picture. At times a suture might be taken for a fracture. He thought that possibly they had not appreciated the picture showing the ventricles; this illustrated a condition never shown before so far as he knew. They had had this patient under observation and all they could say was that there was intercranial pressure. The case had been published with the pictures and he knew of no other similar one. Much could be said by the neurologist on the diagnosis of fractures. Much could be found out without the *x*-ray, especially as to which side was injured. Sometimes it was only on fleeting unilateral symptoms that a diagnosis could be made.

Dr. WILLIAM H. LUCKETT, in closing the discussion, said that he would again call attention to the title of his paper, where it might be seen that he had regarded the Roentgen ray as an *aid* to diagnosis in fractures of the skull. In reference to the case with air in the ventricle there was no air at first, but a week later air was present. They performed decompression, making an opening from behind and air came from the foramen of Magendie. In endeavoring to get a history of when the air had entered, the patient stated that he had sneezed very violently, suffered intense pain, and fluid came from the nose. Probably at this time the air entered the ventricle. Dr. Luckett said he would have to disagree with Dr. Schultze that fractures did not change the shape of the head.

Dr. WILLIAM H. STEWART, in closing the discussion, said that this was a new work and there was no doubt but that they made some mistakes, but he believed the number of those mistakes compared favorably with those of surgery. He appreciated what Dr. Schultze had said about the subdural clot. There was great difficulty in locating those clots; even when one knew the clot was there it was not easy to find it. The interpretation of the plate was important and could only be done by one experienced in the work. Careful technique was necessary, but in the end the method would, he felt sure, be useful to surgery, but it must be remembered that it was only one means and should be associated with clinical history, laboratory reports, and physical examination.

**The Functional Metrorrhagias; Their Nature and Control.**—Dr. ARNOLD STURMDORF presented this paper. He declared that in the daily experience of the gynecologist there was probably not another manifestation with which he was more familiar and of which he understood less than a bleeding uterus. Time-honored dogma had so habituated them to accept every concomitant pathological element as the immediate and direct cause of the bleeding that they had become oblivious to the existence and significance of certain intrinsic intermediary factors that essentially linked cause to effect, and revealed the "why and how" of the uterine hemorrhage in logical consequences. Still less did they know why those uteri bled which presented no palpable evidence of any causative factor; and furthermore they knew nothing of why and how the uterus bled during normal menstruation. Whether the cause of the hemorrhage was apparent or not they promptly inaugurated the same venerable therapeutic trilogy, namely, ergot, packing, and lastly, but inevitably, the curette. If the bleeding continued they renewed their efforts by employing proprietary uterine styptics, and when no further choice remained they resorted to hysterectomy. This, of course, conquered the hemorrhage and left no evidences of their therapeutic impotence, but their clinical conscience might be much disturbed. The two questions to be answered were: (1) Why did this uterus bleed so persistently, and (2) why had they failed to control the bleeding? One after another of the alleged etiological factors failed to exhibit that uniform synchronism essential in order to establish a direct relationship of cause and effect, so that in the present state of their knowledge the title "Functional Metrorrhagia" was justified. These cases occurred most frequently at the two extremes of life and their diagnosis rested on the exclusion of every demonstrable exciting factor. To establish the functional nature of the condition was to establish a favorable diagnosis, for most of these cases, notwithstanding the persistency and gravity of the hemorrhage, tended toward recovery after a more or less protracted period. Coagulation was nature's universal hemostatic and every effort to control bleeding must be an effort to induce coagulation. These hemorrhages presented a perverted menstruation, and any one who had attempted to check a normal menstruation would fully realize the therapeutic difficulties that confronted him in the control of these abnormal types. The incoagulability of the menstrual blood had been noted since the earliest times and the identical coagulability characterized the cases under discussion. For the elucidation of the hematological problems involved Dr. Sturmdorf referred to his former publications on this subject in the *American Journal of Obstetrics and Diseases of Women*, Vol. LXI, No. 6, 1910, and "Studies on Local Hematologics in the Causation of Uterine Hemorrhage," *New York State Journal of Medicine*, October, 1911. The endometrium during menstruation and in hemorrhagic cases received normally coagulable blood from the general circulation and shed this blood in a non-coagulable state. This was due to an inhibiting substance that was periodically secreted by the corporeal endometrium, from which it might be expressed. Such expressed endometrial juice was capable of inhibiting coagulation in any normal blood. The endometrium was activated to the secretion of this substance by a hormone generated in the Graafian follicles. Thus far they had not succeeded in isolating this substance, nor had they discovered its specific antagonist, but they had learned to circumvent it by effectual measures. The object of these measures was the regulation of the systemic blood pressure and the inhibition of the endometrial hyperactivity. Under the guidance of a reliable pressure apparatus, aconite, nitroglycerine, and especially atropine, should be administered until the pressure was normal. Opium was a sovereign adjuvant and was indispensable in cases characterized by cerebral erethism and general restlessness. Ergot was mentioned only to be condemned in the most emphatic terms. It did not and could not control these metrorrhagias. Its influence was not exerted on the non-gravid uterus and it increased the general vascular tension which only tended to increase and prolong the bleeding. The same applied to hydrastin and cotton root bark, while various synthetic oxytocics were absolutely inert. The essayist emphatically condemned the curette except as a diagnostic aid, but held that it had no place in the thereapeutic armmentarium for this form of hemorrhage. Two topical medicaments fulfilled the indications, correcting the perverted function without destroying it, and these were pure acetone and 16 per cent. formalin solution. Either of these agents was cautiously but copiously introduced into the uterine cavity by means of an interuterine syringe of special construction, the end being notched and fenestrated. The syringe held one-half to one ounce. The uterine end was wrapped in thin sterile gauze and introduced into the uterine cavity to the fundus. A free return flow must be assured by the patency of the cervical canal and the vagina protected from the irritating fluid by proper lubrication. The syringe was slowly emptied and carefully withdrawn so as to leave its saturated wrapping in contact with the endometrium for twenty-

four hours. A daily repetition of this procedure was essential. The hemorrhage persisted for several weeks, but was steadily reduced and during this time the treatment must be persisted in. Should this method fail a few applications of the D'Arsonval spark as recently adopted for the treatment of vesical papillomata would yield the desired result. In these cases one should always bear in mind that he was dealing with not merely a bleeding uterus but a bleeding woman. In closing, Dr. Sturmdorf said that during his five years' study much had come to light on this subject and much remained to be solved, but he ventured to assert that no pathologist would ever again have occasion to report that he had deprived a woman of her normal uterus for the control of grave functional metrorrhagia.

Dr. J. RIDDLE GOFFE said this subject had been handled by a master hand; all realized their helplessness before these cases of bleeding without palpable pathogenic condition to account for the hemorrhage. The treatment suggested was based on physiological lines, diminution of blood pressure and treatment of the endometrium. It was only a short time since they were face to face with the fact that there was no cure for these cases but removal of the ovaries or of the uterus. At the recent International Congress in London, Sir Francis H. Champnup, Bart., chairman of the Section of Obstetrics and Gynecology, advised the destruction of the endometrium with nitric acid, and it was maintained that this produced a satisfactory and permanent cure. Dr. Herbert Spencer, the secretary, indorsed his statements. Of course, this treatment destroyed all possibility of pregnancy. He now had three cases under observation in which he had applied the nitric acid treatment and which seemed to be permanently cured. He said that it was a method which he hesitated to use in young women, as it deprived them of successful motherhood, but in advanced years it was indicated and gave permanent results.

Dr. BROOKS H. WELLS said that Dr. Sturmdorf had told them many truths. Functional metrorrhagia occurred in women at the two extremes of life. In young women there was no call for the use of the curette and none for the use of nitric acid. Years ago it had been the fashion to use nitric acid, zinc chloride, chromic acid and even the stick of nitrate of silver. Then all these were abandoned until they were recently resurrected. In young women nothing should be used which would destroy the chance of pregnancy. It was not necessary to examine young women until after drug treatment had been tried. Aconite, calcium chloride in large doses, hydrastis, of which he was very fond but of which Dr. Sturmdorf disapproved, when administered in large doses, had given good results. In cases at the other extreme of life he always tried to make a diagnosis by means of the curette because of the danger of cancer, and this could not be eliminated without getting a specimen. If there were no indications of cancer fuming nitric acid might be used.

Dr. WILLIAM H. LUCKETT said he was much interested to hear that Dr. Goffe had used nitric acid long ago; he too had seen it used many years ago with good results. There were cases in which this was not effective and then one might ligate the uterine artery and once in a while one had to take the uterus out, and then one saw that the blood vessels were very much sclerosed and this might have something to do with the hemorrhage.

Dr. JOHN VANDOREN YOUNG said that no one appreciated more than he the work that Dr. Sturmdorf had done. He wished to add his name to the record as one who would never again take out a normal uterus. They had all been struck by the difficulty of deciding whether hemorrhage in these cases was due to a pathological condition or was simply a functional metrorrhagia and they should thank Dr. Sturmdorf for having called the attention of the general profession to these so-called functional metrorrhagias. The physician was apt to slide over these cases trying one measure after another and that had been his mental state until he had become acquainted with Dr. Sturmdorf's work and had tried to grasp the idea of uterine hemorrhage that was functional. Dr. Sturmdorf's first paper was rather difficult to comprehend and not many knew of the painstaking work put into the two former papers. There was little difference between destroying the endometrium with nitric acid and removing the uterus, of the two the latter was rather to be preferred. If nothing else had been taught except that there was a functional and a pathological metrorrhagia and that it was up to the physician to find out which in a given case, the work of the evening would be productive of great results. It should be remembered that there was nothing more difficult, however, than a positive gynecological diagnosis.

Dr. J. MILTON MABBOT said that a year and a half ago he had sent a case to a specialist and when he got through with her the specialist had said "There, you are all through your troubles now." A few months later she came back and said that she recalled that remark and it seemed like sacrilege. Cures should not be promised and could not be absolutely expected by the patient. In the early and late parts of life these cases went on to cure of themselves and the last man who treated them got the credit.

Dr. E. K. BROWD said that it was not good judgment in these cases simply to take away the uterus; they should remember that, as the speaker had said, they were dealing not with a bleeding uterus but with a bleeding woman. He had had one case in which the uterus was small and the thyroid large. She had been curetted four or five times. He concluded that the bleeding might be due to a systematic condition and administered calcium lactate and thyroid extract, but left the uterus alone. In another case which had been operated upon four or five times a hematoma was found on the ovary which was responsible for the bleeding. Professor Kroenig had just come before them and condemned all attempts at removal and recommended the *x*-ray and radium.

Dr. ARNOLD STURMDORF said in closing the discussion, that in regard to Dr. Goffe's treatment by nitric acid there was one point which he wished to emphasize. Treatment should be directed toward the restoration and not the destruction of a normal function. The nitric acid treatment was a very heroic procedure and while it was safe in the hands of Dr. Goffe it were wiser that the general practitioner should go slowly with it. The endometrium was an organ of internal secretion just as was the thyroid or pituitary gland, and it had other functions with which they were not fully acquainted. The use of the cruette might be followed by permanent amenorrhea and artificial menopause. It was possible to effect all these results through the uterus as well as through the ovaries; furthermore the nitric acid treatment was followed by sloughing of the endometrium and this opened a way for infection and a train of serious troubles. It must be borne in mind that menstruation was a function depending upon a normal ovary *plus* a normal endometrium, and neither of these two essential organs could be destroyed by any form of chemical thermical, or mechanical agent without destroying the menstrual function. In Dr. Goffe's case in which he used nitric acid in a young woman a permanent amenorrhea could be predicted. Dr. Wells had referred to cases that he had cured with drugs; the paper dealt with cases that could not be cured by such measures. The fact that drugs were administered did not necessarily mean that they had caused the cessation of hemorrhage. A tonic contraction of the puerperal uterus lasting forty minutes and over could be produced, but a nonpuerperal uterus cannot be induced to contract for more than forty seconds. It is not a question of impaired contraction but of impaired coagulation with which one is confronted in these cases. The possibility of overlooking cancer had been suggested. It was not intended that any one should run such a risk and he had emphasized in the paper the existence of some insidious forms of adenocarcinoma limited to the upper endometrial zone, the recognition of which was possible only by exploratory vaginal hysterectomy. As to sclerosed vessels as a cause of uterine bleeding, it should be remembered that these were a natural concomitant of senescence and most women with sclerosed uterine vessels did not bleed. One found sclerosed vessels in many brains, yet these brains were not anoplectic, nor did the extravasated blood fail to coagulate.

## MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

*Stated Meeting, Held November* 17, 1913.

THE PRESIDENT, DR. REYNOLD WEBB WILCOX, IN THE CHAIR.

**Osteosarcoma Successfully Treated.**— Dr. J. HERMAN BRANTH presented the patient, a young college student, whom he had shown at the annual meeting of the association in January last, suffering from a recurrence

of osteosarcoma, involving the left lower ribs. When Dr. Branth saw him in June, 1912, he found that he also had a rotary lateral curvature of the spine. The patient was given *x*-ray treatment, combined with the bipolar, high tension, high frequency current, and this afforded relief much more quickly than the *x*-ray alone, which had been employed after an operation nine years before. Another and unexpected relief resulting from the treatment was the marked improvement in the spinal curvature, with reduction of the consequent anterior and posterior chest depressions. The osteosarcoma had now entirely disappeared, and there was little left of the rotary curvature, which Dr. Branth believed to have been of a compensatory nature, and in the treatment of which he had made use of gymnastic exercises.

**The Importance of Early Recognition of Myopathies by the General Practitioner.**—Dr. FRANCIS A. SCRATCHLEY read this paper. He first pointed out the necessity of suspecting all cases in which there were early loss of power and wasting in the muscles (especially in children), whether these pursued a rapid or slowly progressive course. All alterations in the contour of the limbs or changes in gait or other movements, particularly when not preceded or accompanied by other symptoms, should arouse suspicions of myopathy or myelopathy. He urged careful examination with the of the electric currents, and also microscopical examination of the tissues. Early consultation with a competent neurologist was advisable, since the earlier the nature of the condition was recognized, and proper treatment instituted, the better would be the prognosis. In most instances the damage was done early; after which arrest might occur, only to be disturbed by some circumstance causing renewed progression. Among the cardinal characteristics of myopathy were the following: It might appear at any age, but usually occurred in the young, and the disease was more frequently transmitted from the mother than the father. It ran a slowly progressive course, attacking groups of muscles and spreading from muscle to muscle. There was loss of power, with wasting of muscles, though the wasting might precede the other. There was a diminution or loss of faradic response. The muscles were flaccid until wasting was complete. Myopathy might come to a standstill—be arrested or improve. The other symptoms laid down in the books might not be present in all cases of myopathy, and might be found in myelopathy. The speaker's inferences from the recent changes in classification, and from the newer histopathological findings, were to the effect that observers were tending toward the opinion that myopathies and myelopathies were more tha nallied, and it now became a desideratum to find some common cause of origin—such as a neurotoxin, perhaps. The question was still unsettled whether in sympathy the muscles were alone attacked or whether muscles, nerves, and spinal cord cells were all implicated. A simpler classification was urged, as tending toward an earlier and beter diagnosis, which would make the prognosis better. The treatment should preferably be at the hands of a neurologist, since in these cases much depended upon the manner in which massage, passive and active, and electrical agencies were employed.

Dr. LOUIS F. BISHOP said that Dr. Scratchley's effort to point out the practical causes of such troubles, and then reassemble the affections in a few groups, was one quite in line with the present tendency in the progress of medicine. This was clearly shown at the recent international congress in London, where the general aim seemed to be to simplify and find fewer causes for diseases. It was important, he thought, that those in general and hospital practice should bear these myopathic conditions in mind. Every now and then he recognized some patient who had been supposed to be suffering from something entirely different, but in whose case it was found, on careful examination, that the real trouble was one of the muscular dystrophies. Unfortunately, such cases were often misunderstood. While the condition was really a local muscular one, the patient was believed to be the subject of some general wasting disease.

Dr. DAVID E. HOAG said that the chief merit in Dr. Scratchley's paper, he thought, was the getting away from the prevailing nomenclature of the myopathies, which neurologists had seemed to vie with each other in making as complicated as possible. There was probably no condition, or group of conditions, in the whole range of neurology in which there was greater need of elucidation, or which had thus far promised so little in the way of treatment. A professor in a western medical college was said to have once told his students that the pathology and diagnosis of disease did not so much matter; what the public wanted was a "curing doctor." And, so, what the general practitioner wanted was a curing specialist. Too often the specialist, in his consultation work, neglected to give specific directions regarding treatment. Thus, for instance, he should state the relative value of massage and electricity in a given case. If massage were advised, the particular kind of massage should be mentioned; if electricity, the special current to be used and just how and when it should be applied. It was these matters of detail in regard to which the textbooks were so weak.

Dr. FRANK WADE ROBERTSON said that the neurologists had indeed seemed to fairly gloat in finding out new types of myopathies. There was, therefore, much confusion regarding them, and Dr. Scratchley's illuminating paper had distinctly cleared the atmosphere. He agreed with the opinion expressed as to the more frequent heredity on the maternal side. Another point was that at the clinics cases were quite often seen in young children who had been treated for rheumatism. The hypertrophy of wasting was found more particularly in the muscles of the trunk, where the condition was less likely to attract attention than when it affected the extremities. The progress of the disease, as it appeared in children, was apt to be more rapid in cases complicated by gastrointestinal disturbance. He had also found myopathies more frequently following scarlet fever and diphtheria than other infectious diseases. The treatment, unfortunately, was at present very unsatisfactory.

Dr. RANSFORD E. VAN GIESON said that the great number of classifications had arisen, he thought, from the observations of different writers in different cases. The great point to be considered in these cases was whether or not degeneration of the nerve cells was present. If it was, the case was hopeless; although we could not, of course, be sure of such degeneration unless the opportunity for an autopsy were afforded. In cases where there was no nerve cell degeneration he had seen cases not only improve, but entirely recover.

Dr. EDWARD WALLACE LEE said that these cases of muscular atrophy, hypertrophy, etc., were of interest and importance from a medicolegal point of view, because suits for damages were often brought in cases where it was claimed that they had occurred as the result of injuries. Dr. Scratchley's paper was, therefore, of great value in this aspect, as a study of it would enable one to give an intelligent opinion as to the worth of injury as an etiological factor.

Dr. SCRATCHLEY said that a large number of cases were on record in which there was a history of injury. In many of these cases, however, the etiological relation of this was very questionable. Personally, he believed the underlying cause to be some neurotoxic condition, and that trauma was only one of a number of exciting causes.

**Why Electrotherapy Does Not Cure.**—Dr. ALBERT C. GEYSER, in this paper, said that altogether too much was expected from this method of treatment, and only too frequently the showy apparatus and startling electrical manifestations overshadowed the therapeutic possibilities. Honestly mistaken, but deluded, the enthusiast, under the spell of autosuggestion, lauded this agent to the exclusion of all else. A few unexpectedly good results caused the tyro to proclaim his cures as bordering on the marvelous. Yet, electricity applied in some form or other to living tissue was bound to produce some effect. Between the two extremes, electrocution on the one hand and reanimation on the other, lay the great field of electrotherapy. Referring to drug therapy, dietotherapy, hydrotherapy, serotherapy, psychotherapy, and other methods of treatment, as well as electrotherapy, he said that the existence of all these various measures was a certain indication that there was among them not one which could be relied upon as a curative agent to the exclusion of one or more of the others. As a rule, each one was just one link in our therapeutic chain, and only too frequently it happened that the chain was neither strong nor long enough for the desired purpose. Electrotherapy, then, being viewed as just one link in the chain, it was a fact that occasions were met with where the employment of electricity was the proper procedure. In electrotherapy we recognized thirty or more modalities, each one produced in a specific manner and each one capable of producing upon the body specific reactions. Hence the diffi-

culty in selecting the appropriate modality under the conditions present in a given case. Exactly in the same manner, and with the same care, with which a certain drug would be selected and the dose regulated, so should the particular electrical modality be selected and graded as to dose and length of time of application. It, therefore, became apparent that he who would use electrotherapy must be in possession of the means for creating all the various modalities, and be familiar with the physical and physiological properties of these means. Above all should he know the reactions produced by each modality under all the varying circumstances of disease conditions. Without these essentials electrotherapy was a makeshift, and failure to cure would be the result. In illustrating the point, how to arrive at the selection of the indicated modality, a case of neuralgia was taken. The electrotherapist did not treat the *tic douloureux*, sciatica, or supraorbital neuralgia, as the case might be. On the contrary, he saw before him a patient presenting the symptoms of pain in some nerve. He had no stereotyped treatment for the *disease*, but selected his modality according to the reaction desired in that particularly patient. Here was a pain in or about a certain nerve trunk and its immediate branches. While a true neuritis differed in its etiology from so-called neuralgia, clinically we encountered, in many cases, great difficulty in differentiating the two. In the application of electrotherapeutics the results were as satisfactory in the one as in the other, so long as we were dealing with the local treatment of the painful area. An examination of all the various therapeutic measures would show that in reality we were possessed of only two kinds or groups of agents, sedatives and irritants, and in the use of electrotherapy the different modalities enabled us to choose for our local application either a sedative or irritative measure. Under the irritative or revulsive method belonged all those modalities which were capable of causing more or less energetic stimulation upon the cutaneous surface, and especially in the terminal nerve filaments. The faradic high tension current, applied by means of the tinsel brush discharge, was the one in common use. The most efficient of all the irritant measures, however, was the short sparks drawn from a metallic conductor from some static high tension apparatus. There could be no doubt that all these methods frequently showed most brilliant results in neuralgia; it was equally true that all had utterly failed. There must be some underlying principle accounting for this. In medicine we had counterirritants in the form of rubefacients and vesicants. Whatever could be accomplished by such agents could be done by the electrical modalities, with this important difference: the applied dose and resultant effect could be almost mathematically calculated. To properly understand the action of counterirritation we must appreciate the fact that when the central nervous system recognized pain from somewhere in the economy, the moment that a greater irritation was set up at another peripheral point, the original pain ceased to be felt; also the fact that the system acquired under certain circumstances what might be described as the habit of having or interpreting pain. The more successfully and frequently this habit was interfered with, the easier it was made for the central nervous system to forget, as it were, the original chronic pain and substitute for it the pain artificially produced by counterirritation. In neuralgia this might be interpreted that the counterirritation produced upon the terminal filaments caused cessation of the pain in the main nerve trunk produced by some pathological irritation. It was a very simple matter to demonstrate that after the application of some one of the electrical modalities there was a decided change in the pain sense appreciation of the area treated. Such changes lasted from a few hours to a number of days, and tests showed that irritative or revulsive electrical applications caused a long-continued supersensibility. Theoretically we might infer that if the terminal filaments of a certain nerve remained for hours in such a state the pathological irritation from the main branch would be held in abeyance for a greater or less time, according to the reaction produced. The rule could also be formulated that in all cases of neuralgia where the skin overlying the painful area was in a hyperesthetic condition, these and all other methods of counterirritation were absolutely contraindicated; for where the pathological irritation had invaded the terminal nerve filaments the case could only be made worse, because the supersensibility was markedly increased. A point of practical interest was that the treatment with the faradic current should be made only with the tinsel brush, and never with moist sponge electrodes; for the latter allowed the current to penetrate into the deper tissues—a thing we desired to prevent. A drying powder on the skin would cause it to become a very poor conductor, and thus all the faradic counterirritation would be spent upon the surface. The rule should be observed never to attempt to treat an acute case of neuralgia or neuritis by counterirritation; also, never to treat a chronic case without first testing the sensibility of the skin. When the sedation or irritability reducing method was applicable we were at once confronted with the proposition that the pain had already invaded the terminal filaments in the skin, either primarily or secondarily. Any suitable therapeutic agent or method should therefore be capable of diminishing the supersensibility. When an animal was tetanized with strychnine, and the positive pole of a galvanic current was placed over the peripheral end of a nerve, while the cathode rested on the spinal origin of the nerve, we found produced a negative phase of electrotonus, or anelectrotonus. The result was a physiological inhibition of nerve transmission, interference with the transmission caused a failure of response to the toxemia from the strychnine, and the tetanus ceased in that particular nerve. If when a person complained of noises and ringing in the ears after taking quinine, the positive pole of the galvanic current were placed in both ears and the negative pole at the nape of the neck, and the current were passed to the point of tolerance for ten minutes, all the sounds would cease for an hour or more. Such demonstrations warranted us in assuming a similar inhibition in hyperesthesia of a sensory nerve. The older method of using small electrodes and correspondingly small milliamperage had given way to the use of very large electrodes and milliamperage. The galvanic current was indicated in neuritis, especially when such signs as muscular atrophy and disturbed reflexes were present. Another method employed was the use of the static brush discharge, which obtended the terminal filaments by the rapid bombardment produced. Still another method was the use of the high frequency current for diathermic effects. From time immemorial heat had been employed to alleviate pain. When we considered the fact that the externally applied electrodes remained cold, while the tissues between the electrodes could be heated four or five times above the normal, we had a rational explanation of the relief afforded by the diathermic method in such painful conditions as *tic douloureux*. Electrotherapy, therefore, was to be viewed as only one link in our chain of therapeutics; so that if it were employed to the exclusion of the other indicated links it must fail to cure.

Dr. MARCUS NEUSTAEDTER expressed skepticism as to the relief of such conditions as *tic douloureux* by electrical treatment.

Dr. SAMUEL G. TRACY said he could personally testify to the great relief often afforded by the intelligent use of electricity in cases of neuralgia. Even in *tic douloureux* he had seen the pain disappear instantly.

Dr. FREDERICK DE KRAFT said he believed that the reason why electricity so often failed was because those using it did not understand the underlying pathological condition. For instance, many of the cases of muscular weakness following diphtheria were made worse, instead of better, by electrical treatment. Here there was generally a peculiar involvement of the nerves at their point of exit from the spinal canal, and this pathological condition was increased by the injudicious treatment given; with the result of further wasting of the muscles and an augmentation of the palsy. It was a fact, however, that if a very mild constant faradic current were applied to a muscle for four minutes daily for a period of twenty days, its size would be increased 50 per cent. Good results could be expected, he believed, only in the hands of those who carefully studied the pathological conditions encountered and the physiological relations of the various currents. By the intelligent use of high frequency currents we had a means of so affecting the general circulation that the blood would be driven to the periphery. As a result, anemia of the splanchnic area was produced, and in this way we could get rid of the chronic congestion of the liver so often met with in intestinal toxemia, with the production of pain in the form of gouty attacks, neuralgia or so-called neuritis (not true neuritis). Such conditions might often be relieved by thus abating the cause. Many failures in electrical treatment were due to the lack of cooperation on the part of patients who neglected to observe proper precautions as to rest, etc.

### Pathological Society of Philadelphia.

At a stated meeting held January 22 Dr. Charles W. Burr read the report of the Committee appointed at an earlier meeting to present resolutions on the death of Dr. S. Weir Mitchell, one of the founders of the Society, always an active member and its seventh president.

Dr. F. D. Weidman presented a specimen of "Gummatous Scar of the Liver associated with Biliary Abscesses, Septic Phlebitis of the Portal and Coronary Veins and Abscess of the Stomach."

Drs. B. A. Thomas and David Riesman presented a specimen of "Carcinoma of the Prostate, with Secondary Vesical, Ureteral, and Renal Lesions." At one time in the history of the case the symptoms were supposed to be dependent on the presence of vesical calculus, but when the real cause was determined it was too late for any hope from operative intervention. Through studies of the eliminative function of the kidneys by means of phenolsulphonephthalein it was possible to demonstrate the progressive degeneration of those organs.

Dr. Robert N. Willson, Jr., demonstrated "Specimens of *Filaria sanguinis hominis* from a Patient seen in 1898." They were obtained from a patient from the west coast of Africa admitted to the Pennsylvania Hospital at the date named and who informed the examining physicians that his blood contained interesting objects. Examination in the evening showed active filariæ over a considerable period of time.

Dr. Willson also discussed "A Case of Splenomyelogenous Leukemia, with 800,000 Leucocytes to the Cubic Millimeter." The patient was a Hebrew who was advised operation for removal of the spleen in one hospital and promptly left this institution to enter the Philadelphia General Hospital, where he died a few days after admission. Examination of the blood disclosed the large number of leucocytes mentioned and of these a considerable proportion were myelocytes.

Dr. Willson also demonstrated the brain from "A Case of Meningitis." The patient was a man admitted to the hospital in a state of persistent and unyielding coma, with a leucocytosis of 20,000 and evidences of nasal disease and mastoid involvement. There was no response to treatment, and death ensued. On post-mortem examination a disseminated purulent meningitis was found, most marked at the base, with suppuration of the ethmoid sinuses and necrotic disease of the mastoid on one side. Obviously the extension had taken place through the ethmoid bone to the meninges.

Drs. John A. Kolmer and Augustus A. Eshner presented specimens from "A Case of Hodgkin's Disease, with a Diphtheroid Bacillus, Corynebacterium Hodgkini." The patient was a man, 28 years old, who after chills, fever, vomiting, and diarrhea observed enlargement of the glands in the groins, the axillæ, and the neck, and on examination in addition the spleen was found to be enlarged. Section of a removed gland exhibited the characteristic histological picture of Hodgkin's disease and inoculation of various culture media resulted on the twenty-second day in the development of a granular diphtheroid bacillus, which was, however, finally lost by overgrowth of *Bacillus subtilis*. Culture from another gland resulted in the growth of a solid diphtheroid bacillus, and the histological picture of sections of this gland, while distinctive, differed in some respects from that originally observed. The man presented slight irregular elevation of temperature for several weeks, the number of erythrocytes and of leucocytes and the percentage of hemoglobin were about normal, the percentage of polymorphonuclear leucocytes 65 per cent., that of small lymphocytes 30 per cent., and that of eosinophiles 3 per cent. Donovan's solution of mercury and arsenic was administered and applications of *x*-ray made and reduction in the size of the glands followed. Also a small dose of a vaccine from the organism isolated was administered, but this gave rise to no reaction.

Drs. B. A. Thomas and Robert H. Ivy presented a communication entitled "Observations on the Wassermann Reaction." They pointed out a number of ways in which error might arise in the making of the test and the clinician accordingly might be led to false conclusions with respect to both diagnosis and treatment.

Dr. Frank B. Block read a paper entitled "The Effect of Operation Upon Renal Excretion as Indicated by the Elimination of Phenolsulphonephthalein." It was found that little if any change was brought about in the elimination of urine as a result of anesthesia and surgical procedures with respect to both healthy and diseased kidneys.

Drs. J. A. Kolmer and C. P. Brown presented a communication entitled "A Study of Complement-Fixation in Gonococcus Infections." They found a positive reaction in upward of 60 per cent. of cases. The results were naturally more constant the longer the existence of the infection and the more deeply situated it was. Accordingly, while a negative response may be of little significance a positive response must be looked upon as diagnostic.

---

### Philadelphia Psychiatric Society.

At a stated meeting held January 9 Dr. Frank Woodbury, secretary of the Pennsylvania State Lunacy Commission, read a paper entitled "The State Care of the Indigent Insane." He gave an account of the historic development of the care of the mentally deranged in Pennsylvania and pointed out the inadequacy of the present method of operation. As a result hospitals in all parts of the State are overcrowded, while deserving patients cannot be given care and treatment to which, especially by reason of the nature of their ailment, they are entitled. He made a plea that all hospitals for the insane should be under State care, utilizing pre-existing institutions and making expansion from them as centers of development. There is urgent need for psychopathic wards for the care of acute or suspicious cases, as well as departments especially for curable cases and for incurable cases capable of performing certain tasks and thereby contributing, in however small a measure, to their own support and maintenance.

The discussion was participated in by Dr. Mitchell of Warren, Pa.; Dr. E. F. Brush of Towson, Md.; Dr. Owen Copp, Dr. J. Allen Jackson, Dr. Charles K. Mills, Dr. A. R. Moulton, Dr. T. H. Weisenburg, Dr. George E. Price, Dr. J. H. W. Rhein, Dr. J. Madison Taylor, Dr. W. W. Hawke, Dr. F. X. Dercum.

Dr. Francis X. Dercum delivered the presidential address, the subject of which was "An Evaluation of the Psychogenic Factors in Mental Diseases, Including a Review of Psychoanalysis." He considered the etiology of mental diseases, placing the greatest stress on the factor of neuropathy in the causation, and in conjunction with which a large number of other factors might be operative. He delivered a most scathing criticism of psychoanalysis, designating it as a form of mysticism, without scientific basis, exhibiting a sort of epidemic prevalence that eventually must undergo subsidence and relegation to the storehouse of discarded theories.

**Paradoxical Tachycardia Associated with Arterial Hypertension.**—A. Mougeot points out that in the absence of any disorder of the auriculoventricular conducting mechanism, persistent arterial hypertension of a moderate degree is associated in most instances with a tachycardia of from 80 to 120 pulsations. The reason why the name paradoxical has been applied to this phenomenon is because it apparently contradicts the law of Marey, namely, with increased arterial pressure there is a diminished pulse-rate and vice versa. But this law applies only to the normal individual. In pathological hypertension there are certain accessory phenomena that reverse Marey's law. Mougeot tested the oculocardiac reflex in case of paradoxical tachycardia accompanying hypertension. This reflex consists in a slowing to the extent of eight beats of the pulse upon compression of the eyeball. There is a positive response in cases of paradoxical tachycardia of hypertension, showing that the vagus nerve has retained its normal excitability.—*Le Progrès Medical.*

**Keratosis Follicularis Spinulosa.**—J. L. Bunch reports a case of this condition in a child, aged 2, on whose scalp and eyebrows no hair had at any time grown except a number of stumps, darkly pigmented, and ⅛ inch long. Round each pilosebaceous orifice was well-marked keratosis, and to the touch the surfaces gave the sensation of a nutmeg-grater surmounted by very small bristles. No redness or hyperemia was present, the disease gave rise to no apparent subjective sensations, and the child seemed to be otherwise in good health. Microscopically, no fungus was present in the hairs. A younger sister had a good crop of healthy hair. The name keratosis follicularis spinulosa was given to the disease by Unna, and appeared preferable to the name keratosis pilaris.—*Proceedings of the Royal Society of Medicine.*

## Books Received.

GEUNDSATZE FUR DEN BAU VON KRANKENHASSERN. By Dr. THEL. Paper; 170 pages; price 6 mks; illustrated. August Hirschwald, Berlin.

## Miscellany.

**Quackery in the Eighteenth Century.**—Tobias Smollett, who was a member of the medical profession, delineated in Ferdinand Count Fathom a vivid picture of the contemporary quack. Fathom took lodgings over an apothecary's shop, and advertised that every day at a certain time and place he would give advice to the poor for nothing, hoping that some lucky cure might bring him fame and patients. In the meantime his chariot rolled during the whole forenoon through all the most frequented streets, and at the usual hour he never failed to put in an appearance at the medical coffee house, where he mingled freely with the company there. "The other means used to force a trade, such as ordering himself to be called from church, alarming the neighborhood with knocking at his door at night, receiving sudden messages in places of resort, and inserting his cures by way of news in the daily papers, had been so overdone that they had lost their effect on the public." Fathom, therefore, decided to wait till he should have acquired interest enough to erect a hospital by the voluntary subscriptions of his friends—a method which had paved the way to success for many doctors. But even in the middle of the eighteenth century it "was so overdone that almost every street was furnished with one of these so-called charities."—*British Medical Journal.*

**The Medical Historian.**—A writer in the *Lancet*, October 4, 1913, points out that the history of medicine is a subject which has of late years attracted far more attention than formerly. The Royal Society of Medicine has organized a section of the History of Medicine, and in addition, also for the first time, a section in the same subject has formed part of the proceedings of the recent International Congress of Medicine. The history of medicine is a study of very many, and at first sight, of widely divergent, matters, and the ideal medical historian would be a man of encyclopedic knowledge. He should know Greek, Latin, and Arabic, to mention only the three principal languages, as well as his own tongue. He should have a knowledge of paleography; he should be an accomplished physician and surgeon; he should have a knowledge of ecclesiastical history and the lives of the saints, and in addition he should be no stranger to anthropology and folklore; for the history of medicine is a part, and no mean part, of the history of human intellect and of search into the two great mysteries of life and death. Primitive medicine was, and is still among the few primitive races that are left, mainly concerned with amulets, charms, and incantations.

**An Automobile Danger in Winter.**—In cold weather the first explosions of an automobile engine are apt to be irregular and uncertain. An explosion in one cylinder will warm up that one, and to some extent the next one, while the others may remain cold. This irregularity tempts one to advance the spark more than it should be advanced for safety.—*Motor.*

**Safety First.**—A clipping bureau has collected accounts of over twenty-two hundred broken arms from "kickbacks" last year. The damage done in this one year would offset the expense of placing self-starters on half the automobiles in the United States.—*Motor.*

### INTRAVENOUS INJECTIONS OF SODIUM SALICYLATE IN THE TREATMENT OF RHEUMATIC AFFECTIONS.*

By LEWIS A. CONNER, M.D.,

NEW YORK.

(From the Department of Medicine of the Cornell Medical College and the First Medical Division of the New York Hospital.)

The well-known irritant effects of sodium salicylate upon the stomach of many patients and the complete intolerance to the drug of certain susceptible subjects has led to various attempts to find some satisfactory substitute for the usual method of mouth administration. Thus the drug has at times been given by rectum, and has been applied to the skin locally, and attempts have been made to use it by subcutaneous injection. This latter method has been found impracticable because of the painfulness of such injections, the local irritation, and the large quantity of solution required. A modification of the hypodermic method was introduced by Bouchard, who sought to obtain a local effect by the injection of a weak (3 per cent) solution of the drug into the periarticular tissues of the inflamed joints. This method has had some vogue in France, but has gained no widespread popularity.

In 1904 Felix Mendel[1] demonstrated the feasibility of the intravenous administration of sodium salicylate and published the results of his experience with such intravenous injections in the treatment of various rheumatic affections. In selected cases he claimed for this method certain decided advantages over the usual mode of administration by mouth, basing his conclusions upon a series of over 300 injections. If certain special precautions were observed the method, he found, was free from danger and was usually quite painless. In a few instances the injections resulted in thrombosis of the vein at the site of puncture which, however, soon subsided without any unpleasant sequellæ. Among the cases so treated were included examples of acute, subacute and chronic articular rheumatism, sciatica, lumbago, pleurisy, and peliosis rheumatica. The advantages claimed for this method were the avoidance of the unpleasant stomach symptoms; the absence of prostration and profuse sweating; the prompter and greater relief of pain, and greater effectiveness in the treatment of certain types of rheumatic trouble. He obtained very striking results in the relief of pain in all sorts of rheumatic affections whether the lesions were localized in the joints, muscles or serous membranes. The method he thought was especially useful in severe cases of rheumatic fever in which the usual mode of treatment produced little or no effect; in cases in which the inflammation tended to persist indefinitely in one or two joints, and in cases of monarticular rheumatism without fever. The treatment he found had little or no effect upon the temperature in rheumatic fever. and he did not recommend that it be employed as a substitute for the usual method in the routine treatment of such acute cases.

Mendel's results were verified, to some extent, by Behr,[2] Rubens,[3] and Winkelmann,[4] who saw the same striking analgesic effects and who found the injections, under proper precautions, painless and free from danger. On the other hand Brugsch[5] could see no advantages in the intravenous injections over the ordinary form of administration and both he and Doevenspeck[6] found them frequently painful and liable to local complications. The method thus far seems not to have gained any general or widespread application.

The aqueous solution used by Mendel contained, in addition to sodium salicylate, a small quantity of caffeine sodio-salicylate, the object of which was to render the injection painless by its local anesthetic action. Two cubic centimeters of the solution (representing about 6 grains of sodium salicylate and one grain of caffeine) were injected at intervals of from 12 hours to one or two days. Mendel insisted that freedom from local complications (pain, inflammation, thrombosis, etc.) could be insured only if special precautions were observed in giving the injections. The point upon which he lays great stress is that the vein to be used must be of large size in order to avoid the local irritant effect upon the endothelium which is likely to cause thrombosis. In most cases the vein, he thinks, should be dilated by the procedure of letting the arm hang down for several minutes, with the fist tightly closed and with an elastic ligature upon the arm to prevent the venous outflow. By repeating this process two or three times it is possible to dilate even relatively small veins to a size sufficiently large to render the injections painless and free from the risk of thrombosis. Mendel advised that, as far as possible, a fresh vein be used for each injection.

My own experience with the intravenous administration of the drug is limited to 12 cases of articular rheumatism of various degrees of severity in which about 130 injections were used. This number while too small to justify any sweeping assertion as to efficacy of this method of treatment is yet sufficient to give some indication as to its practicability and its freedom from objectionable side effects. We very soon found that in order to obtain any really satisfactory results the drug had to be used in considerably larger doses (from 10 to 20 or even 30 grains) than that employed by Mendel. In these larger doses we found that the amount of caffein contained in Mendel's solution was sometimes objec-

*Read at the 259th meeting of the Practitioners' Society, January 2, 1914.

tionable, and as the caffein seemed to serve no very good purpose it was omitted and the sodium salicylate was used alone in a 20 per cent. solution. A very important factor in determining whether or not the injections were painless and free from the risk of local thrombosis was found to be the size and character of the needle employed. We at first used a needle of the size commonly employed for blood cultures and occasionally this was followed by thrombosis at the site of puncture. When, however, we began using a very small hypodermic needle and were careful to see that it had a fine, sharp point, this difficulty ceased immediately and it was found that the same vein could be used over and over again without the slightest pain and without local irritation or thrombosis.

Mended noted that the solution changed rapidly on exposure to light and air, the colorless liquid soon taking on a reddish or brownish tinge; and he insisted that only the fresh and colorless solution was suitable for intravenous use. The commercial form of synthetic sodium salicylate usually dispensed is an amorphous powder and solutions of this, we have found, usually show an amber or yellowish color almost as soon as made. In our first cases, in which this form of drug was used, an injection would occasionally be followed by a chill or by vomiting. When, however, a change was made to the chemically pure, crystalline form of sodium salicylate the solution was perfectly colorless and would remain so for several days if protected from the light; and with this solution we have never had a chill or an unpleasant symptom even when doses of 30 grains were given.

In my experience, therefore, the two most important points to be observed in the giving of the injections are: (1) to use only a very fine, sharp needle, so that the trauma to the vein wall may be as slight as possible; and (2) to have the solution fresh and made with chemically pure, crystalline sodium salicylate.

The technique employed at the New York Hospital is as follows: A stock solution is made by dissolving 10 grams of c. p. crystalline sodium salicylate in 50 c.c. of distilled water which has been freshly sterilized by boiling. The drug is weighed and handled as aseptically as possible and the solution after being made is not subjected to further sterilization. The solution should be perfectly colorless and, if protected from the light, will keep for several days.

A rubber ligature is applied to the upper arm sufficiently tightly to prevent the venous return flow and, if necessary, the venous engorgement is increased by letting the arm hang down and by closing and opening the fist. The skin about the flexor surface of the elbow is sterilized by painting it with tincture of iodine. A 10 c.c. all glass syringe, carefully sterilized, is filled from the stock solution, each cubic centimeter of which contains 3 grains (0.2 gm.) of sodium salicylate. A fine, bright, sharp hypodermic needle is used. With the patient's arm fully extended and the vein fixed below by pressure of the left thumb the needle is thrust into the vein in the direction of the venous flow. In order to be certain that the point of the needle is within the lumen of the vein the piston is then slightly withdrawn. If a drop of blood appears at the mouth of the syringe the ligature is loosened and the proper quantity of solution injected. As the needle is withdrawn from the vein gentle pressure is made for a moment at the site of the puncture to prevent leakage of the blood into the subcutaneous tissue, and the iodine is then washed off with alcohol. No dressing is required for the tiny wound in the skin. In case a good sized vein is available in each arm it is well to use the arms alternately, but we have found no difficulty in using the same vein for a number of successive injections when necessary.

The size of the individual dose and the frequency of the injections will vary with the requirements of the individual case. As has been said, we have found it necessary to use larger doses than those employed by Mendel in order to obtain distinct effects. In most cases the dose has been either 15 or 20 grains and the injections have been given at 12 or 8 hour intervals over a period of from 3 to 6 days. Occasionally, in robust men, as much as 30 grains have been given at a time and as much as 120 grains given in the first 24 hours without any unpleasant effects whatever. Indeed one of the noticeable features of this method of administration, in my experience, has been the entire absence of shock, prostration or other objectionable constitutional effect.

Emphasis has been laid by certain writers (Lüthje,[7] Brugsch[8]) upon the irritant effects upon the kidneys of large doses of the salicylates, especially if continued for a considerable period of time. In the cases treated by me intravenously no such effects were observed when the drug in daily amounts of from 75 to 100 grains was continued over a period of several days.

As regards the therapeutic effects of the intravenous use of sodium salicylate in rheumatic fever my experience has been that the relief of pain is prompter and more pronounced than is usual when the drug is administered by mouth. It has been a common occurrence to see a patient, who had been suffering intensely, obtain almost complete relief from pain for a number of hours after an injection, and to look forward with impatience to the time for the next injection. In one extremely severe case, in which 130 grains a day by mouth was given for three days with no effect whatever, improvement was seen almost immediately after the intravenous injections were begun.

In the case of a young girl, whose intolerance to the drug by mouth was complete, the intravenous injections produced immediate relief and a rapid cure.

In spite of such examples of marked benefit, however, I am by no means convinced that the intravenous method is, in general, more effective than the usual one, and I am far from feeling that it should replace the method of mouth administration for routine cases.

That it has a field of usefulness, however, I am convinced. It solves most satisfactorily the problem of the treatment of those patients who are quite unable to retain the drug when given by mouth. It should be tried in patients who show little or no response to the usual method of treatment. In cases in which the pain is intense it seems to me worth while to begin the treatment with a few intravenous injections before resorting to the usual method. Finally the injections seem to have distinct advantages over the ordinary method in cases with threatening heart complications and in the treatment of severe rheumatic affections of the eye, by reason of their more rapid action and accurate dosage. Sauton,[9] who reports a number of cases of rheumatic iritis so treated, emphasized the prompt relief

of pain and believes that the course of the disease is shortened and the chance of recurrences lessened by this mthod.

*Summary.*—To summarize briefly it may be said that, with the proper technique and with a chemically pure preparation of the drug, the administration of sodium salicylate by intravenous injections is safe, painless, and easily performed. So administered the drug seems to have a much more pronounced analgesic effect than when given by mouth. While it seems unlikely that the intravenous method will replace the usual one in the routine treatment of rheumatic fever, it nevertheless has a distinct field of usefulness, the limits of which cannot yet be determined. At present this field seems to include cases in which the drug is not well borne by the stomach; those which show little or no improvement under the usual mode of administration; those with beginning heart complications, and, possibly, cases of severe rheumatic inflammation of the eye.

## A STUDY OF PROSTITUTION IN EUROPE

By DOUGLAS C. McMURTRIE

NEW YORK.

The control of prostitution is, to say the least, a highly controversial subject. Opinions of competent experts have ranged between the widest extremes.

In the resulting polemic there has been much vigorous discussion between the advocates of varying methods proposed for dealing with the social evil. Leaving aside for the moment matters of detail, the question has hinged on the decision as to whether the public authorities should in any way supervise or control the actual system of prostitution. Those who believe in the wisdom and justification of such a course are said to believe in "regulation." Those who believe such a system to be an improper function of the State, pernicious in its exercise, are termed "abolitionists," by reason of their desire to "abolish state control of vice."

Prostitution is essentially an urban problem; its organization is extensive in the great cities of the world. The centers of large populations among civilized peoples are practically restricted to Europe and North America. In the United States and Canada there can be said to exist or to have developed no specific system of dealing with prostitution. In fact, until very recently, little attention has been accorded the subject at all. Individual communities have met their most acute problems of police jurisdiction in various ways; some form of segregation was the usual solution. There has been, however, constant advocacy by certain persons of the advisability of introducing some system of regulation.

No such system, however, can be said to have been given a reasonable trial in the United States. An experiment was made in St. Louis some years ago, but was soon abandoned, and a recent introduction of medical inspection and supervision of prostitutes in San Francisco has been inconclusive in results. We can, therefore, not look to American experience for a settlement of the relative merits of the systems of dealing with prostitution.

In Europe, however, the situation is different. The great cities of the Continent, unlike our own metropolitan communities, have had large populations for many years. The prostitution problem with them is not a new one and they have been dealing with it for a long time. There has been extensive experience and the resulting methods developed have varied widely. Both extremes of regulation and abolition, in addition to the intermediate stages, are represented. There are also communities which have had experience under both systems.

In some of the European cities extensive regulatory systems have been in operation. Extravagant claims with regard to the advantages derived have been advanced by their advocates—claims which on the face of them were too preposterous to be believed. On the other hand, the abolitionists attacked the systems in a most intemperate manner, making statements which were too sweeping to be credited. The accounts of any given situation were almost exclusively partisan in character and thus valueless from a judicial point of view.

In Europe, therefore, was available a rich fund of experience, while the opinions respecting the prostitution question were conflicting to the point of confusion.

Believing that an impartial study and description of the European methods of dealing with prostitution and their results would aid in the solution of problems which are in the United States becoming more and more pressing, the Bureau of Social Hygiene retained Mr. Abraham Flexner to make a personal investigation on the ground. The findings of this study have just appeared* in a volumne which recounts the first-hand experiences of the author. The purpose of the book is a laudable one and much of the material presented is of unique value. Any attempt at a critical evaluation of the work will be deferred until later in the present article.

The scope of the work is defined as a study of prostitution "from the standpoint of the practical experience of European countries. An effort will be made to ascertain its forms and extent, the sources from which it is recruited, the conditions that either cause or conduce to it, the procedure of different communities in dealing with it and with the conditions responsible for it, the measures which have been employed by way of combat or control, and the results which have been thus obtained. Material will be drawn from extended personal inquiry and observation in the larger cities of England, Scotland, France, Italy, Belgium, Switzerland, Holland, Denmark, Norway, Sweden, Germany, Austria-Hungary—from the countries, in a word, that may be grouped as Western Europe, because they are characterized by a considerable degree of similarity in all that pertains to social life, national ideals, and political institutions." In detail the following cities were visited: London, Liverpool, Birmingham, Manchester, Glasgow, Edin-

*Abraham Flexner: "Prostitution in Europe." Introduction by John D. Rockefeller, Jr. Publications of the Bureau of Social Hygiene. New York: The Century Company, 1914; pp. ix, 455.

burgh, Paris, Lyons, Rome, Brussels, Berlin, Hamburg, Dresden, Frankfort-on-Main, Cologne, Hamm, Stuttgart, Munich, The Hague, Amsterdam, Rotterdam, Copenhagen, Stockholm, Christiania, Geneva, Zurich, Vienna, and Budapest.

The definition of prostitution involves several difficulties. The police authorities have arbitrary criteria and historical authorities have adopted varying formal distinctions. The experience of the author leads him to "consider prostitution to be characterized by three elements variously combined—barter, promiscuity, emotional indifference. The barter need not involve the passing of money, though money is its usual medium; gifts or pleasures may be the equivalent inducement. Nor need promiscuity be utterly choiceless; a woman is not the less a prostitute because she is more or less selective in her associations. Emotional indifference may be fairly inferred from barter and promiscuity. In this sense any person is a prostitute who habitually or intermittently has sexual relations more or less promiscuously for money or other mercenary consideration. Neither notoriety, arrest, nor lack of other occupation is an essential criterion. A woman may be a prostitute, even though not notorious, even though never arrested, even though simultaneously otherwise employed in a paid occupation.

"The scope of the term is thus greatly, and, as I hope to show, justifiably, nay necessarily, extended. Barter, emotional indifference, and more or less promiscuity do not in modern cities characterize the sex relations of the avowed or professional prostitute alone. They are equally characteristic marks of the clandestine prostitute, using the term in its literal meaning to designate the numerous class of professional prostitutes whose real character is known only to their own clientele and their close female companions; of the occasional prostitute—women who alternately emerge from and relapse into an irregular life; of the incidental prostitute—those who carry on more or less prostitution without interrupting some honorable employment; of women who practise prostitution under cloak of other occupations; of women, who, ceasing to be kept as mistresses, practise prostitution as a stop-gap until a firmer footing is once more found; of women who reserve themselves by express arrangement for a small group, none of whom can alone afford their support; of women, who, faithful to one individual at a time, are still taken up by a succession of men paying for favors; finally, of married women, by no means always of the lowest classes, who, perhaps irreproachable in the eyes of the world, are not above earning through ignominy the price of luxuries. Here are eight different categories, falling outside the narrow conception of prostitution, if prostitution is conceived to be characterized by barter, emotional indifference, and promiscuity."

Prostitution is found to be objectionable for one or more of several reasons: in the first place, because of the personal demoralization it entails; in the second, because of economic waste; again, because it is the main factor in the spread of venereal disease; finally, because of its intimate association with disorder and crime. The count on the score of venereal disease might be even more emphatic; prostitution is the sole reason for its existence to any appreciable extent.

The conclusions regarding the prostitute class are in a certain respect decidedly optimistic. "What becomes of the ordinary prostitute? For the common notion that her expectation of life is some five or sir years, there is no basis in fact whatsoever. It is demonstrably untrue even of the avowed professional or registered continental harlot. . . . Prostitutes disappear rather than die—a fact of great practical significance as we shall discover; only a part—it is uncertain of what size—remain prostitutes; a small fraction marry, a much larger fraction return to work; those who stick to the business wind up as the servants of younger prostitutes, occasionally as brothel-keepers; a few of them are found as aged hags, offering themselves for a copper coin below the bridges of Berlin or in the dark corners of Whitechapel." On this basis the ultimate fate of the prostitute is menacing but not entirely hopeless.

Any estimate of the cost of prostitution to the community must be more or less fantastic. According to Flexner, "of the total loss only the roughest guesses can be made; but it is worth noting that any estimate that endeavors to include all factors, direct and indirect, soon reaches into the millions. Losch, for example, has reckoned the annual cost of prostitution to the German Empire at something between 300 and 500 million marks. This outlay may be contrasted with that spent by the Prussian Government on its entire educational system; its universities, secondary schools, elementary school system, technical and professional institutions of all kinds involving a budget in 1909 of a little less than 200,000,000 marks. Assuredly the economic burden imposed on society by prostitution is comparable with that due to standing armies, war, or pestilence."

So much by way of introduction. The present review will endeavor to bring out the points of the study which have especial interest from the medical point of view.

Homosexuality is given brief mention. "Prostitution in Europe as an organized business is by no means limited to the intercourse of persons of opposite sexes. A homosexual prostitution—prostitution, that is, in which the parties belong to the same sex—has developed on a considerable scale. Notorious resorts for those addicted to homosexuality are to be found not only in Paris but in smaller towns, like Hamburg. Berlin is, however, probably the main mart. In prominent thoroughfares, bars exist to which only women resort as well as bars to which no woman gets access; and at intervals, large homosexual balls are given, attended only by persons of a single sex. I witnessed one such affair, at which some 150 couples, all men, appeared. It is estimated that between 1,000 and 2,000 male prostitutes live in Berlin; forty homosexual resorts are tolerated by the Berlin police; and it is reported that some 30,000 persons of marked homosexual inclination reside in the German capital." It may be mentioned in passing that the question of homosexuality has received extensive attention in Germany.

At Berlin was found one of the best systems of medical inspection, the bureau charged with this duty having been completely reorganized in recent years. The requirement regarding frequency of examination depends upon the age of the prostitute: if under twenty-four, twice weekly; between twenty-four and thirty-four, weekly; and over thirty-four, fortnightly. Any registered prostitute is also examined whenever she may be arrested for any offense. Clandestine prostitutes may

be examined under compulsion at the discretion of the bureau chief. Such examination is made by a woman physician; the inspection of the registered women is delegated to male physicians.

The staff consists of eight police physicians and four microscopists of whom four are on duty at a time.

The hours are from nine to twelve and from twelve to three, daily except Sundays, and on this latter day provision is made for those whose situations so require. "The examination consists of a clinical inspection and the use of the speculum. For the detection of gonorrhea, microscopic examinations of the secretions are made fortnightly in case of women under 34; monthly in case of older women. At any time, however, when appearances are suspicious, the physician is instructed to ask for a microscopic examination without waiting for the regular day. Female assistants are provided for this work; the word of the assistant is sufficient in case the microscopic preparation is found to be negative; the physician must by his own observation confirm a positive result." The Berlin bureau presents, strange to relate, the only instance in Europe of expert medical control of this sanitary function, Dr. Georg Güth being the present director.

When inscribed women are found to be infected they are confined "under duress in a municipal hospital, on the theory that, being professional prostitutes, who can maintain themselves only by plying their business, they must be interned in order that the carrying on of their business may be temporarily suspended. In very rare cases, however, even when found to be diseased, they are permitted to retain their freedom provided an approved physician makes himself responsible for their systematic treatment, and provided, further, that there is reliable evidence to show the possession of resources which will enable the women in question to keep their engagement to refrain from plying their vocation for the time being. Women are also at times released from the hospital on condition that they report at intervals for further treatment; should this understanding be violated, they are once more interned. Clandestine and occasional prostitutes if found diseased on being arrested are somewhat differently managed. If without resources, they are sent to the hospital; but the bureau chief may, in his discretion, permit them to remain at large on condition that they place themselves in charge of a competent physician. It is, however, admitted that pledges, whether given by clandestine or registered women, are not to be relied on. At both hospital and police headquarters in Berlin conscientious and intelligent efforts have been made to provide satisfactory arrangements. Registered and non-registered women are scrupulously separated at every stage, on the ground that the latter group may contain young, innocent, or, at least, not yet hardened persons, who should not be further contaminated by the carelessness of the State. Premises not adapted to this end have, therefore, been extensively remodeled. The rooms utilized for the medical examinations at the police headquarters are light and equipped with a modern examining-chair, hot and cold water, and electric light; the microscopic room has the necessary equipment for clean and accurate work. The hospital, though old and small, has been latterly renovated and its staff reorganized. The present medical chief of the police division in charge of venereal disease is a specialist of distinction, who has made important contributions to the literature of the subject on both medical and sociological sides. The division possesses an excellent laboratory manned with trained assistants; and it is properly equipped with microscopes, culture-ovens, animals for experimental purposes, etc. Patients are examined separately in a clean, well-lighted room, containing all necessary paraphernalia. Women at different stages of demoralization—registered, non-registered, first offenders—are scrupulously kept apart; clean and orderly as the women are in appearance, there is nothing in their demeanor or surroundings to suggest prison confinement." The above description is based on extensive personal observation and interview.

The regulation system of Paris is probably more referred to than any other. It is certainly the most widely known from the historical point of view. The conditions are not encouraging; from the hygienic point of view they are quite the opposite, to say the least. According to Flexner "all day long a dismal succession of groups of abandoned women file into the rudely equipped rooms in which two physicians ply their repellant task perfunctorily. A line is formed; with open jaws and protruding tongue they march rapidly past; the doctor uses one spatula for all, wiping it hastily on a soiled towel from time to time. This finished, the same group in quick succession ascends two surgical chairs to permit a cursory vaginal inspection; the physician, stationing himself between them, loses no time, for one women is assuming the recumbent position while he is engaged in the examination of another; he switches back and forth as rapidly as the women can get up and down—indulging in good-humored and sometimes unseemly jocularity as the work proceeds. Of the two physicians employed on the occasion of one of my visits, one used a rubber glove, the other a rubber finger—in both cases the same for all; though wiped on a towel from time to time, neither was changed or cleansed. On one occasion I observed one of the physicians examine 25 or 30 girls without changing, washing, or wiping the rubber fingers he wore; and a number of those examined were adjudged 'diseased.' The speculum was rarely used. In one instance, pressure by the finger on the urethra discharged an abundant suspicious secretion; the same finger, unwashed, was used in examining the next case; in another instance, the same rubber finger was used on the genitalia and about the mouth. The inspections consumed from 15 to 30 seconds each; 'for vaginal examinations,' so read my notes made on the spot, 'it takes less time to examine one woman than it takes another to mount the examining chair and offer herself for examination, despite the fact that her clothing has been adjusted before entering the room.'" And this constitutes sanitary control of prostitution in Paris!

Perversion is rampant in modern prostitution, largely for the reason that it is highly profitable. This is especially the case in the established house. "The bordell is a veritable school of abnormality. The Paris bordells are elaborately equipped for every conceivable form of perverse indulgence. The inmates compete with one another in forcing upon the youthful customer the knowledge of unnatural and artificial forms of sexual gratification. Similar excesses are practised elsewhere—indeed wherever the bordell is found. The Swedish

women told Dr. Lindblad that 'the girl-house is the main seat of perversity; soon,' they added, 'Stockholm will be as bad as Paris.' The infamous implements employed are in full view as one enters the apartments in Helenenstrasse. The degradation of the bordell inmate is total; her rehabilitation well-nigh impossible. She fares worse than the street-walker, who sometimes returns to an orderly manner of life."

The relation between alcoholism and prostitution figures largely in the study. This differs not at all from the determinations of American experience; the saloon is handmaiden to the brothel. The psychology of the matter is about as follows: alcoholic intoxication decreases actual sexual capability but it greatly increases sexual enterprise, the illusion of capability. Further, it renders inoperative the inhibitions of caution, prudence, and the like which are usually in force. Thus Flexner notes that "the sale of alcohol in the bordell markedly increases the range of infection, for it provokes recklessness and banishes caution. It has been estimated that one-third of the gonorrheal infections are incurred while the victim is in liquor" and again: "In Möller's cases at Stockholm 67.7 per cent. of the infected men admitted intoxication." Further "one of the most disgusting aspects of bordell life is the forced consumption of alcohol; the customer on entering is plied with drink; and, of course, the inmates share; conviviality is procured by general and continuous indulgence in beer, wine, and champagne. In order to prevent complete physical disorganization on the part of the women and to restrict the commerce in volume, the sale or use of liquor is forbidden in the bordells of Brussels, Altona, Hamburg, Stuttgart, Bremen, and other cities. But it goes on openly and flagrantly, nevertheless." Everywhere prostitution and the sale of drink are in close connection.

The various first hand accounts given by Flexner of conditions in European cities simply go to show that medical inspection at its best is usually inferior. It is, however, well known at the present time, that no clinical examination will surely detect the presence of venereal disease. The best that can be done is to detect virulent states of disease in a few women and effect their confinement for a ludicrously short period. They then return to their business. Every prostitute is in a chronic state of venereal disease; there is no safety in prostitution.

Segregation practically does not exist in Europe, probably more on account of moral considerations than those of order or sanitation.

Flexner has satisfactorily demonstrated that the European regulation systems, first, are not essential to the preservation of order, and, second, do not conduce materially to the reduction of disease. He has further demonstrated that as good results on the scores of both order and health are obtained under abolition conditions. The undoubted statement is made that whatever reduces the volume of promiscuous coitus is the most potent factor in limiting the spread of disease. There have been carefully considered and discussed the various statistics and authorities bearing on these points.

The appendices giving translations of the regulations in Paris, Berlin, Hamburg, Vienna, and Denmark are extremely valuable to students of the subject.

The book is the only one in English treating of the working of the prostitution systems of Europe. Its preparation involved careful work on the part of a trained observer, and the result is such that no student of the subject can neglect.

On the other hand, however, there are some features still to be covered. The present writer had read a reasonable amount of the polemical literature regarding regulation and abolition. What was lacking, however, was a visualization of the actual conditions in the various European capitals. At no point in the book, for instance, is there any description of what the prostitution situation is in Paris today. Nor is there any consecutive description of conditions in Stockholm or Rome. Certain selected features only have been described in the discussion of certain points. Without questioning the validity of the conclusions, the reader cannot feel sure that another might not go over the same ground and the same literature and prove almost the opposite thesis. In special pleading such as is under present consideration the method does not seem the most convincing possible. A faithful survey of vice conditions in the various individual European cities still needs to be written if the American reader is to be in possession of all the facts.

It is to be regretted that a book of such permanent scientific value and upon the compilation of which such great pains had been bestowed was not more carefully proofread. Such words as *faithful, originally, duties,* and *surveillance* are misspelled. In a casual reading without checking at all the original sources I found twenty-three errors of spelling and typography and nineteen errors in style, these numbers not including lack of uniformity in the spelling of words such as *gonorrhea* and *moeurs* nor in the anglicization of geographical names.

The index is deficient; some of the best known authorities on prostitution who were quoted in the text are entirely omitted, while inconsequential citations are listed. This is a serious lack in a book of the character of the one under review, as it makes it impossible to locate material for specific purposes.

One final word, and this only a suggestion. The question of prostitution in its relation to health is manifestly shifting from inspection of the prostitute to protection of her client through the means of personal prophylaxis. So far as I can discover the employment of preventive measures is on the increase in Europe today and the German student who elects to take his chances in the maze of prostitution is placing more reliance on his own safeguards than on any government oversight of his partners. At present this subject is clouded and confounded with moral considerations, but it seems destined to have an important relation to the prostitution of the future.

## THE SURGICAL ANATOMY, DIAGNOSIS, AND TREATMENT OF THE INFLAMMATORY AFFECTIONS OF THE NASAL ACCESSORY SINUSES IN CHILDREN.*

By SEYMOUR OPPENHEIMER, M.D.,
NEW YORK.

Inflammatory affections of the nasal sinuses occurs more frequently in children than is generally

*Presented at the meeting of the American Academy of Ophthalmology and Oto-Laryngology, held at Chattanooga, September 26, 1913.

considered. Not only does this statement apply to the adolescent, but also to the small child and infant. From a study of the surgical anatomy of the nasal accessory sinuses, it does not seem improbable that some instances of meningitis are the result of unrecognized sinusitis. This can readily be appreciated from the structure of these parts, as there is great variation in their size and shape; they are surrounded by much softer bone than occurs later in life; there is greater development of the vascular and lymphatic systems, and the mucosa is in intimate relation with the osseous tissue, so that inflammation of the former produces some pathological changes in the latter.

My experience has been that chronic sinusitis is not as frequent as in the adult, but both acute and subacute sinusitis are common and it will be found that many instances of postnasal catarrh are but symptoms of some inflammatory condition of the adjacent sinuses.

Case I.—C. M., a boy of 12 years, following measles three years previously had a constant discharge of mucopus from the postpharyngeal region. Two years later I first saw him and found his pharynx and nasopharynx in good condition and that the discharge of which he complained, came from the posterior nasal cavities on both sides. The turbinals were but slightly congested and swollen, but after careful repeated observations, it was found that the trouble was confined to the posterior group of ethmoid cells on both sides. After free drainage was obtained through surgical intervention no further trouble was experienced, the discharge ceasing entirely.

In connection with the anatomical development it should be remembered that the maxillary sinus is well defined, although rudimentary at birth, and even in the fetus it is found about the fourth month, so that inflammation of this sinus at an early age is not infrequent. From this early form which represents the adult sinus but in miniature proportions and which has a triangular shape, it undergoes but little change until the second dentition, when the development of the molars and bicuspid teeth play an important part in its relation to the bones of the face. In the new born it is situated internally to the orbit and does not sink below it until some time later, while its mucous membrane lining which is tenuous in the adult is exceedingly thick, so that it almost fills the small cavity, leaving but little space in which pathological fluids might accumulate.

Previous to the completion of the first dentition, the odontoblasts are in most intimate relation with the floor of the sinus, which is usually high, reaching about to the attachment of the inferior turbinal body. The floor of the antrum in the child previous to the second dentition is on a line with the nasal floor and it is not until a later age that it becomes lower as in the adult type, but it does not reach the latter type until about the twelfth year. The increase in size of the antral cavity occurs principally at the expense of the alveolar process, which is in part absorbed with the resultant downward enlargement of the cavity, when the thickest wall is then found to be formed by the body of the superior maxillæ posteriorly, while the orbital wall superiorly is of extreme tenuity. Of all the walls of the antrum, the nasal aspect is the most important, not only surgically, but also from a diagnostic standpoint; on account of its tenuity and from the fact that at this point visible pathological changes are found in immediate conjunction with the natural stomata. Much previous to this, however, accessory foramina are found, but not as frequently as in the adult and the stomata opens into the middle meatus at the posterior end of the semilunar hiatus.

Most important in the child are the inflammatory affections of the ethmoid cells, these cells and the antra being more frequently involved than the frontal and sphenoidal sinuses. Evidences of the ethmodial area are seen in the fetus about the fifth month and distinct cells are frequently found at birth; often more, eight to ten being found during the first year and from that period on, these tissues are susceptible to morbid changes, the cells reaching their maximum development about the eighteenth year. Frequently these cells are rudimentary, however, and occasionally one finds a misplaced cell that makes it rather difficult to locate the various parts with any degree of accuracy. In the child as in the adult, the middle turbinate body is essentially a portion of the ethmoid area, although its anterior end is thinned out, is small, and runs parallel to the perpendicular plate, so that the lower border is deflected inwards.

At about the eighth to the tenth year, one finds that the ethmoidal ostia open into the nasal meati and for surgical purposes and especially in the recognition of morbid changes, the cells can be grouped into an anterior mass communicating with the middle meatus, while the posterior group opens into the superior meatus. The anterior group is by far the most important, as its stomata are found along the semilunar hiatus and the fissure between the ethmoidal bullæ and the inferior turbinate body, at a location where infection from intranasal morbid changes most frequently takes place. The anterior cells are more numerous than the posterior, although the latter are larger as regards the capacity of the individual cells, but their stomata are much less in size than those of the anterior mass.

As the internal wall of the orbital fossa forms the external boundary of the ethmoid, the possibility of orbital symptoms as a complication of ethmoidal infection, is apparent. In operating upon this region, this relationship must be borne in mind on account of the extreme thinness of the orbital wall and the danger of injuring the contents of the orbital cavity.

Case II.—C. D., one year. Measles. Profuse mucopurulent discharge from both nostrils during the course of the disease. After convalescence continuation of discharge from left nostril. When seen, considerable unilateral orbital cellulitis and swelling of cheek. Proptosis conjunctival ecchymoses. Ectropion. Discharging sinus at lower angle of orbit. Probe passed into sinus entered area of roughened bone in ethmoidal region. Operation. Puncture of maxillary antrum through nasal wall with positive results. Incision of orbital sinus and incision over and removal of portion of nasal process of superior maxilla to expose ethmoidal tract, which was then removed with cutting forceps. Convalescence uneventful.

Previous to the seventh or eighth year, the frontal sinus is usually not developed to any extent, although from the second to the third year it is not uncommonly found as a mere trace of a cavity. Rather infrequently, it is present as early as the fifth year as a definite cavity subject to pathological changes, but before puberty it does not extend far up in the frontal bone; then a marked change takes place continuing until the eighteenth year, when its full development is accomplished. It must always be borne in mind that the frontal sinus is a sequence of the cellular expansion of the anterior group of ethmoid cells—into the diplopia of the squamous portion of the frontal bone, and that

in the treatment of inflammatory conditions here, the intimate relationship with the ethmoid region must always receive due consideration. The anatomical and surgical relations differ in no way from that in the adult, excepting that its relation to the cranial cavity on account of the thin posterior wall, is most intimate, and this must be considered in relation to inflammatory processes.

The sphenoidal sinus may show as a depression in the cancellated tissue of the sphenoid body even at birth and a definite cavity may be present at the fifth month, although of necessity it is a mere slit in the soft osseous structures. A definite cavity being found as early as the third year, while by the twelfth year, it is well developed and while its inflammatory changes have not been as much studied as have the other sinuses, yet I am of the opinion that it is more frequently involved than is usually considered. Strangely, however, it seems that the capacity and size of the sphenoid cavity is most erratic and the age of the child will give little information as to these factors, as a study of several anatomical specimens will usually show marked variations so that a young child may have a comparatively large cavity and a much older child will have a very small one. Its lateral walls are largely within the intracranial cavity and especially is this to be considered in relation to the development of obscure cases of nasal meningitis, as is also its intimate relations laterally and superiorly, with the internal carotid artery and cavernous sinus.

Case III.—M. S., age three. History of unusually frequent coryzas. Nasal diphtheria followed four weeks later by temperature, neck rigidity, double Kernig and convulsions.

Examination:—Excoriated upper lips. Slight anterior nasal discharge. Much mucopus in nasopharynx. Child semi-comatose and moribund. Death. Post-mortem inspection of nasal chambers. Middle turbinates and septum removed to expose the sphenoid. Anterior wall of sphenoid removed and cavity found to contain large quantity of pus. Culture. *Streptococcus pyogenes*. No cranial post-mortem allowed, but it seems likely that the meningitis was directly the result of the nasal accessory cavity infection.

The recognition of sinusitis in the child is more difficult than in the adult, as the symptoms are usually obscure; are rarely characteristic, and it is rather unusual to have a single sinus involved to the exclusion of the others, the rule being that more than one sinus is affected at the same time. Under such circumstances, one can well appreciate the difficulty of differentiating individual inflammatory areas. When the superior sinuses are the seat of a purulent inflammation, the discharges may infect those lower down, especially the maxillary antrums, so that the soft tissues around the stomata are kept irritated and swollen, and it becomes most difficult to determine the exact primary condition.

The frequency of the infectious diseases in childhood and the concomitant inflammatory changes of the nasal mucosa, explains why the sinuses should be involved during this period and especially does this occur in influenza, scarlet fever, measles, pneumonia, and diphtheria. In the vast majority of cases, there is a primary inflammation of the nasal mucosa and the sinuses become involved from direct extension of this inflammation, irrespective of its basal cause, the swelling of the soft tissues around the sinus opening, causing the secretions to be retained as a result of the stenosis thus produced. Unlike that which may occasionally occur in the adult, sinusitis in the child is practically never of primary origin, the close relationship of these tissues with the nasal mucosa being such that when the latter is inflamed from any cause the former must invariably be simultaneously involved.

In the newborn, antral sinusitis may occur as a result of infection by vaginal discharges from the mother or from injury, the result of instrumental delivery, and the resultant purulent inflammation involves the soft, osseous antral walls. In my experience this condition arising from these causes, or others in small children, is a true sinusitis as definite as that found in the adult, and it is not a tuberculosis caries, or osteomyelitis, as has sometimes been claimed. As a rule, affections of the antrum occur during the second dentition, while infrequently errors in the development of the teeth may act as an exciting cause of the empyema. In such cases the relation of the teeth to the maxillary cavity must be carefully considered and the radiograph alone will clearly elucidate the conditions along the alveolar process.

The ethmoid labyrinth in the older child is especially liable to become involved in all inflammatory affections of the nasal mucosa and in coryza. In the contagious diseases, these cells are affected in practically every instance; to my mind, accounting frequently for the manifest suppurative ethmoiditis in later life, which has in reality existed from early childhood.

The recognition of the various sinus affections in the child is more difficult than in the adult, as the subjective symptoms are not clearly defined. Great weight should be attached to the intranasal findings. Transillumination in my hands as a method of diagnosis has proven of great value providing it is used in connection with a regulating rheostat to measure the intensity of the illumination. I have found of considerable use when its introduction was possible the electrically illuminated pharyngoscope, as one can explore readily the nasal areas and the recognition of posterior ethmoid and sphenoid disease is much facilitated. The use of carefully made Roentgen plates is of great service, especially as regards the presence of pus in the antra, or frontal sinuses, and previous to the tenth year the use of the stereoscopic radiograph is the most valuable single diagnostic medium that we possess. A markedly swollen mucous membrane, however, will give a shadow more clearly than the presence of pus in a sinus.

The presence of frequent headache should always occasion suspicion of sinus inflammation, as should also tenderness to touch over the suspected sinus, such a symptom, however, being of practical value mostly as regards the frontal sinuses, bearing in mind that localized pain is difficult to ascertain with accuracy in the very young. When headache is present, however, it is most important as part of the general complex of symptoms, but its absence indicates nothing and as a symptom alone without other intranasal signs it is of no value from a diagnostic standpoint. In acute sinusitis, pain of an aching character or acute, neuralgic in type, even like that of the adult, is almost invariably present at some time during the course of the inflammation, but in chronic cases it is frequently absent, unless the secretions are retained under pressure, when it may become most intense; but it must be remembered in this connection that the degree of pain in the head very often bears no relation to the severity of the inflammatory process of the particular sinus involved. A dull pain between the eyes, however, in the presence of other intranasal symp-

.oms, is strongly indicative of ethmoid involvement.

A marked symptom of great diagnostic value when present is the cessation of pain with the appearance of free nasal discharge, and the return of he pain when the discharge lessens or temporarily eases. The presence of discharge especially if unilateral and purulent, or semipurulent in character, s always of diagnostic value and especially if intermittent; but the presence of pus in the nasal chambers is in small children not necessarily indicative of sinus disease, while at the same time it is important to remember in this respect that the absence of pus does not necessarily mean the absence of a purulent sinusitis. Curiously in purulent sinusitis in children the nasal chamber may be entirely free from pus during irregular periods of the day, so care must be taken in considering this, as serious errors may ensue. If there is lymphoid tissue in the vault of the pharynx, most marked on the side from which this discharge comes, it will often be found that the adenoids alone are not the source of the continued coryza from which the child suffers, but n addition there is a sinusitis. The location of he discharge is of great value in determining which sinus is affected, and the method of ascertaining his differs in no way from that in the adult, which s so well known as to require no further discussion here. At the same time it is important to bear n mind that the pus may be inspissated, or of such a thick character, that it will not drain freely, so that at certain periods of the day it is apparently absent, while on the other hand, if purulent fluid should be present in the nasal chamber it is a positive indication that a particular sinus is involved, if the fluid rapidly continues to reappear in he same location as soon as it has beeen removed. Such a symptom being indicative of the fact that a collection of pus of some standing is present, as t cannot be secreted in this manner from the mucous surface.

Aprosexia and disturbance in the general health are more or less inevitable concomitants of chronic purulent sinusitis and not infrequently it will be found that there is a daily rise of temperature of a degree or more, while in addition the pulse will be more rapid than normal. Complications are possibly not as frequent as in the adult, although orbital symptoms are not uncommon. In the socalled strumous child, where there is a purulent nasal discharge, with excoriated upper lip and marginal blepharitis, with frequently corneal ulcers, purulent sinusitis usually of the antrum and ethmoid cells exists, and while serious organic osseous changes are not present, yet when they do occur the ethmoid structures are the ones most frequently involved. The formation of polypoidal degeneration as in the adult is most infrequent, and usually when it does occur in my experience it is strongly indicative of a latent specific basis. In purulent inflammation of these sinuses, and especially in that acute fulminating type sometimes seen, serious orbital complications may ensue as a result of pathological changes in the correlated vascular sinuses, with the devlopment of thrombosis of the cavernous sinus and resultant pyemia, meningitis, and death. In the milder form, a symptom not uncommon and always of diagnostic value, is edema of the eyelids from vascular pressure.

In inflammatory processes affecting the maxillary antrum, it is not uncommon to find some involvement of the osseous structures of the superior maxillæ if he purulent sinusitis is long continued, and in children under one year of age a true maxillary empyema may occur with the development of abscess and fistula in the infraorbital region, but in the majority of instances the affection presents rather a benign course and is only too frequently unrecognized and treated as "nasal catarrh." After cleansing the nasal chamber, the reappearance of pus in the middle meatus is indicative of antral suppuration, appearing most often beneath the middle turbinate. In older children, puncture of the lateral nasal wall of the antrum is necessary to establish the diagnosis of the condition present. In very small children this procedure must be performed most cautiously.

As a result of neglected rhinitis, inflammatory changes in the ethmoid structures are frequently found, but it has been my experience that isolated sinusitis is uncommon. In younger children the antrum is apt to be simultaneously involved, while in older children the frontal sinus may be also affected, and, not infrequently, it will be impossible to differentiate between a frontal sinusitis and an ethmoid affection, in which the anterior cells of the latter are involved, but for practical purposes this is of little moment. On account of the relation of the complicated ethmoid system to the other sinuses, and the fact that pathological changes occur here so frequently as a result of the various infectious diseases, it will be found that this sinus is the primary source of infection in the great majority of cases of pansinusitis, and that this relationship is especially emphasized on account of the intimate connection of the various stomata of its component cells with the other sinuses, so that a purulent discharge here is almost impossible, without involving other sinuses to a more or less degree. The difficulty of diagnosis in such cases is also enhanced by the variations in the location of the stomata of the sinuses involved, as the variations in their location are so frequent that in the soft tissues of the child the accurate recognition of the particular sinus involved, in a given case, may present most grave difficulties. Anatomically, this becomes evident when one recalls that the ethmoid mass occupies at least one-half of the space between the cribriform and the nasal floor, and therefore its various cells each with its own stomata, are peculiarly subjected to the brunt of any inflammatory changes which take place.

As a result of the late development of the frontal sinus, as has been previously pointed out, chronic changes are unusual, but its involvement in the older child during acute intranasal inflammation is much more frequent than actually considered.

Case IV.—M. T., female, age 12 years, had a severe attack of coryza five months ago, which her physician stated cleared up in about ten days, with the exception of a periodical headache over the right supraorbital region and a semipurulent discharge from the nares of the same side. Two weeks later she complained of a dull ache constantly present, over the right frontal sinus, which became most acute about ten o'clock each morning and lasted for about two hours, when the extreme pain would subside coincident with a free discharge of purulent fluid from that side. There was considerable tenderness to pressure over the sinus and examination showed the left nares normal, while on the right side there was marked turbinal engorgement and a purulent discharge coming from the middle meatus. The radiograph showed a shadow on this side, while all the other sinuses were apparently normal. The use of warm saline irrigations were without effect and as the symptoms were not relieved after several days of this treatment, it was deemed advisable to resect the anterior end of the middle turbinal, which gave free access to the sinus, and irrigations, followed

by the injection of a week argyrol solution, were followed by the prompt disappearance of both headache and purulent discharge.

The recognition of inflammatory changes in this region does not differ from that in the adult, and the presence of pus in the middle nasal meatus may greatly aid in establishing the diagnosis, although it may be easier to eliminate suppuration of the frontal sinus than to define its presence. The value of a well made radiogram in defining the surgical aspects of the frontal sinus, as to its presence or absence, height, depth, etc., is of the utmost importance. The pain is apt to be more localized over the affected sinus than that which occurs in other regions, and while it is often dull in character it is at times violent or throbbing and is accompanied with local tenderness.

The recognition of purulent sphenoidal sinusitis is by far the most difficult as it is practically always combined with ethmoidal changes and the symptoms are not characteristic. Severe occipital, or vertical headache with more or less dizziness, is suggestive of retained secretions; the discharges are scant and usually become inspissated in the nasopharynx, or along the posterior portion of the vomer and floor of the nasal chambers, and it will be found that not infrequently the condition cannot be recognized until exploration has been made of the interior of the sinus.

The routine use of the pharyngoscope in young children has disclosed a surprisingly large number of cases of posterior ethmoidal and sphenoidal suppuration which would have been unrecognized by any other method of examination.

Most important is the fact that these inflammatory invasions mean a radical disturbance of the entire drainage system of the nasal interior, and all treatment, whether conservative or radical, must rest upon this basis.

The treatment of sinusitis in the child should always aim to destroy as little tissue as is consistent with obtaining permanent results, and as far as possible the nasal mucosa should be preserved if operative measures are employed. Palliative treatment will permanently cure the majority of acute sinus inflammations, where such treatment is intelligently directed toward free drainage and the reduction of inflammation. Previous to the employment of surgical measures, therefore, the use of warm alkaline sprays, or normal salt solution and a weak epinephrin solution to reduce the congested mucosa, with, if the case is severe, rest in bed, the employment of laxatives and such general measures as may be indicated, will often produce the most happy results, and in this connection it should be remembered that the tendency of acute sinusitis is toward cure. The local employment of cocaine in these acute cases is usually unnecessary and is to be deprecated. Much relief may, however, be obtained by the external local application of heat or cold, or the use of the steam atomizer.

Where the sinus disease has continued and resists treatment it may be found that the general health of the child has been impaired previous to the development of the nasal affection, as a result of the original disease causing it, and until proper care of the general health is instituted local measures may not be of much avail. It would be well under such circumstances to obtain a culture of the microorganisms present in the sinus, and to have prepared an autogenous vaccine which may increase the opsonic index and powers of recuperation. Intranasal treatment I believe to be primarily indicated in all cases of sinusitis in children, but it should be strongly emphasized that the turbinal tissue should as far as possible be preserved, and while it is necessary at times to remove the anterior end of the middle turbinate body, yet the removal of its entire structure to reach the stomata of any of the sinuses is not warranted.

As an example of intranasal treatment in such conditions:

Case V.—M. L., female, age 6 years. Unusually well developed and healthy child. Had an attack of influenza of unusual severity, six months before coming under my observation. This was accompanied with profuse purulent discharge from both nares, which completely ceased on the left side within a few weeks, but has continued on the right ever since.

When she came to my office the left nasal cavity was normal, as was also the pharynx, but the right cheek was tender to pressure and she complained of more or less constant dull pain over the infraorbital region. The right nasal chamber contained pus, which when removed reappeared in the middle meatus. As it was impossible to enter the sinus through the natural opening, a puncture was made in the thin lateral nasomaxillary wall, and a metal cannula was left *in situ* through which irrigation was practised every day for two weeks, then at less frequent intervals until at the end of five weeks no trace of discharge could be found, when the cannula was removed. No evidence of any nasal suppuration has manifested itself since, being now two years.

When possible, drainage should be obtained through the natural openings, and to accomplish this it is proper to remove enough tissue at such points as may be required. It should be remembered in this connection that the greatest caution must be exercised in any operative procedures involving the superior portion of the nasal chambers, as in the child, the anterior segment of the cribriform plate is especially thin, where the branches of the olfactory nerve penetrate and is particularly susceptible to injury with possible serious results.

When the frontal sinus is involved its relation to the anterior group of ethmoid cells is such that attention must be paid to them before the inflammation of the mucus lining the frontal sinus will subside. When the antrum is diseased inflammatory changes as a rule readily subside under ordinary treatment, but in obstinate cases, after fracturing and pushing aside the inferior turbinate body, a large opening should be made through the inferior meatus into the sinus and the parts drained in this way, the use of irrigation or not depending upon the character and chronicity of the purulent discharge. Aspiration and subsequent lavage are indicated in older children instead of more radical measures, when the antrum continues to discharge pus and does not respond to the usual treatment.

The following case illustrates the conditions that prevail when the ethmoid area is involved:

Case VI.—C. E., male, 12 years. Had a severe rhinitis which resisted treatment for six weeks, when I first saw him. He complained of dull headache all over the head; a purulent discharge from both nares and inability to breathe through the nose. Both middle turbinals were swollen and occluded. The meatus, and considerable pus came from the ethmoid region. Under shrinking with adrenalin, followed by warm saline irrigations, the purulent discharge completely ceased on the right side, but it was necessary to open the anterior group of ethmoid cells on the left side before the pain in the head disappeared, and the purulent discharge entirely ceased.

In some fulminating forms of sinusitis in the child and in the persistent suppurative cases resisting endonasal treatment, with impairment of the general health, or violently acute symptoms, exter-

nal operation will be indicated, bearing in mind, however, that previous to any radical external operation in the child a careful examination should be made for any morbid changes in adjacent areas which may be keeping up the sinusitis by interfering with drainage, as it has been my experience that in not a few instances treatment for a considerable time may be of no benefit until an hypertrophy of the middle turbinate body has been removed, or possibly an adenoid mass in the nasopharynx which has acted as a constant source of reinfection. It should be emphasized that the enlargement of the middle turbinate body is a serious obstacle to the cure of inflammatory changes in any sinus, and until this has been relieved the sinusitis may prove most obstinate to treatment. The attempted removal of purulent material in the child, by suction or negative pressure, has not in my hands been of much value, and I am not certain but that it has exercised a harmful effect.

Free drainage must be secured before cure can be obtained and if intranasal treatment fails to obtain such a result, then whatever radical operation may be selected should be performed. It should be also emphasized in this connection that free drainage means free nasal respiration, and this is another prominent factor which must be taken into consideration in the surgical treatment of these conditions. In addition, it is essential that whenever pus is found in any of the sinuses it must be evacuated as a surgical principle. On this basis rests the surgical treatment of all chronic sinus affections, with the various modifications of technique in the care of individual sinuses, dependent upon the peculiar anatomical structural characteristic of each.

When the external radical operation on the frontal sinus is under consideration it is essential therefore as a preliminary step to remove the anterior portion of the middle turbinate body in order to secure thorough drainage. The external operation on the frontal sinus in the young should be performed with the greatest reluctance in the absence of external or intracranial symptoms. When it is necessary to operate on this sinus it is well to attempt an osteoplastic procedure and to form an anterior bony flap.

In those cases where the frontal sinusitis has been unrecognized, a fistula may have resulted and the condition has possibly been treated as a dacrocystitis. The only method by which relief may be obtained is by thoroughly opening the sinus externally, cleaning out the ethmoid cells which are always concurrently involved, and obtaining free drainage through the nasal chambers. Before performing a radical external operation for frontal empyema on the child it is well to remove the entire group of ethmoid cells.

In children the antrum rarely requires external operation, as opening through the lateral nasomaxillary wall the irritation is usually sufficient to cure the suppuration. In the absence of the diseased osseous tissue or new growths, external operation is never indicated; a large opening through the pars membranacea giving better results in every way than a Caldwell-Luc operation. In young children operative work upon the maxillary antrum must be performed with great caution on account of the relation of the teeth at this age, as such procedures during the formative period of the teeth are apt to result most disastrously.

In conclusion, as a result of my experience, I believe that in young children radical external operative procedures for the relief of purulent sinusitis are infrequently indicated, and are not as productive of satisfactory results as intranasal procedures, and while the same may be said of older children, yet in such, when the sinuses approach the adult type, the same indications for treatment and operative procedures apply as in the adult.

45 East Sixtieth Street.

## CARDITIS

By GEORGE MONTAGUE SWIFT, M.D.,

NEW YORK.

The cause of diseases of the heart in so many of the children who come under care in St. Mary's Free Hospital for Children—about fifty cases each year out of about seven hundred and fifty medical admissions—has been a constant subject of study during the whole period of my twenty-seven years of service at the hospital. The great amount of investigation that has been carried on by many workers during the last few years has done much to elucidate the question, and has enabled me, by piecing together points gathered from many sources, to develop, for myself at least, what seems a satisfactory explanation of the cause and course of carditis.

For several years it has been evident to us at St. Mary's that the cause of heart disease and also of acute joint disease in children had in most cases to do in some way with the infections occurring about the nasopharynx (adenoids, ethmoidal cells, tonsils), but especially with the infections of the gums and alveolar processes which have been irritated by the presence of decayed teeth. If we removed these sources of infection and improved the condition of the nasopharynx and gums, in most cases of acute cardiac disease, distinct and immediate improvement occurred in the condition of the child. The continuously elevated temperature would subside and the child would practically recover, though often with a murmur remaining; the presence of a cardiac murmur however, without more definite signs and symptoms of disease we have learned to ignore. Many children are admitted for various reasons to the hospital, in whom a murmur is present, but with no other signs of illness, recovery having already occurred from the acute process causing it. These facts we had learned from clinical experience, but the definite cause of carditis we had failed to grasp.

In an article by Cary Coombs, of Bristol (*Journal of Pathology and Bacteriology*, 1910-1911), on "Microscopic or Submiliary Nodules of Active Carditis," there is a report of a most painstaking investigation of the nodules found by Coombs and other observers, in the hearts of people dying from cardiac or rheumatic conditions. "These nodules were found scattered throughout the myocardium, in the valves, subendocardial and subpericardial; they were rarely found in the walls of the auricle, and more in the left ventricle than in the right. The central fibrous body, or that zone of muscle which borders on it, is especially liable to develop nodules; there is the closest relation between the distribution of the nodules and the coronary arterial system, so close that some sections recall periarteritis nodosa. The nodules may lie in the periarterial connective tissue at a little distance from the vessel; they may develop in the arterial

*Read before the New York Clicinal Society, October 24, 1913.

adventia enwrapping the vessel in it, or they may begin in the arterial media, swelling and bulging the wall of the vessel on one side to such an extent as almost to obliterate the lumen. In the valves it is clear that the nodule begins in the depths of the valve, possibly spreading towards the surface; also there is loss of substance in the endocardium; nodules are also found throughout the pericardium."

In the same article Coombs also says that the rheumatic germs are distributed through the coronary vessels. His main point is that the nodules are peculiar to the rheumatic condition, and that other infections cause other lesions without these peculiar nodules. To me however, the main point of interest in Coombs' report is the demonstration that the infections are distributed by means of the coronary system of blood vessels—a pathology quite different from that which most of us were taught. I find also that Coombs at the meeting last summer of the British Medical Association, in his remarks on "Affections of the Heart in Childhood," states his points with great clearness, but says nothing concerning the nodules. I abbreviate his points: (1) Rheumatism is a streptococcal infection. (2) The infective agent enters the body in many cases, if not all, by the lymphoid tissues of the nose and throat. (3) Its attack on the heart is executed through the heart's arterial channels, and is delivered simultaneously upon all parts of the heart wall. The microscopic character of the inflammatory foci found in the myocardium as well as in the other tissues attacked, shows that the organisms enter through the arterioles. (4) Progress of the infection is not steady—it consists of a series of active phases, separated by periods of absolute quiescence. (5) These attacks come close together and so probably the streptococci are resident in the body. (6) It is in its tenacity, rather than its virulence, that the chief danger of the rheumatic infection lies. (7) The heart is a muscle, and it is only by crippling its muscular functions that disease can overcome it.

To me the especially interesting point of Coombs' remarks, is the definite statement, based on his careful investigations, that the infecting organisms are distributed through the blood vessels of the heart, and yet this point seems to have excited no interest, at least no discussion at the meeting where the remarks were made.

Thomas Lewis, of London, in a most lucid lecture (*British Medical Journal*, March 2, 1913), also describes the myocardial involvement and localized inflammatory lesions due to infections, and he also is impressed with the idea that there is a difference between the infection by the rheumatic organism and other infections, though the signs produced by their local inflammatory foci are the same. In this case also, to me, the main point of interest is that Lewis also recognizes the general infection of the heart, and especially the involvement of the myocardium.

During the last year Rosenow and Leila Jackson, of Chicago, in two separate articles in the *Journal of Infectious Diseases*, September, 1912, have reported results of their experiments on animals with the organisms obtained from tonsils of people sick during the milk epidemic. They used rabbits and guinea pigs and found after injecting the material into the animals, that the organisms were scattered throughout the heart causing multiple embolic processes in the capillaries of the valves, and in the vessels of the myocardium, endocardium and pericardium—in other words, there was a general cardiac infection. The organism for the most part was found to be *Streptococcus viridans*. Leila Jackson, in her experiments, found the nodules to contain the infecting organisms. It seems to me that these results, added to the findings of Coombs, already referred to, point to something definite, and indicate that an acute infection distributed through the coronary vessels is the cause of carditis. The nodules are the result of the inflammatory action excited by the local infection.

The young men working last winter at St. Mary's were able to demonstrate in the blood of several cases of acute cardiac disease the presence of the *Streptococcus viridans*, and in one case at autopsy not only was a streptococcus found in the pericardial effusion, but it was also scattered throughout the myocardium and endocardium; there was besides a definite embolic process in one of the larger branches of the coronary artery with abscess formation. All this coincides perfectly with Rosenow's findings in his rabbits. Another case at St. Mary's of staphylococcic infection of a finger, showed upon autopsy the staphylococci distributed throughout the myocardium and endocardium, demonstrating that in this case also the infection was a general one. The results of these investigations, and the demonstrations of the presence in the blood of organisms which upon autopsy are found distributed throughout the different parts of the heart, have convinced me, looking at the question from the standpoint of a clinician, that this is the correct explanation of acute cardiac disease. We must learn to look upon acute infections in the heart just as we do on acute infections elsewhere and recognize that the infecting organisms are distributed in the course of the coronary vessels. The difficult thing for some of us, who have been trained to believe that the term rheumatism really means some actual but undefined condition, is to free our minds of this idea. For though for some years I suppose most physicians have accepted the demonstrations that acute articular inflammations—the so-called acute articular rheumatism—are due to acute infections, perhaps of some peculiar organism, we have not acted upon that belief, and have continued to think and act as though we believed rheumatism meant something more, and could act as the cause of endocarditis. I believe we should absolutely drop this indefinite idea, and accept the fact that acute articular inflammations as well as acute cardiac inflammations are due to infections; with this postulate we have no difficulty in gaining a perfectly clear conception of the subject. We ought to look upon cardiac infections as exactly similar to infections elsewhere, *i. e.* as a septic process, the septic organisms being carried and distributed by the coronary vessels and causing more or less localized lesions.

The theory which guides our action at St. Mary's is somewhat as follows: infecting organisms are taken up by the circulation from some part of the nasopharynx, adenoids, ethmoidal cells, tonsils, or as I believe more commonly from infected gums or alveolar processes about decayed teeth. Of course, the organisms may be absorbed from any point where there is a septic process, a finger, an extremity, the genital organs, the intestinal tract, the bronchi or lungs. These organisms having an es-

pecial affinity for the heart are distributed through the coronary system of vessels causing multiple embolic processes; frequently the capillaries of the valves are affected, setting up a valvulitis with perivascular exudation; or the vessels of the endocardium may be plugged and cause a loss of tissue, an ulcerative process; or the vessels throughout the myocardium are involved with perivascular exudations and occasionally an abscess; or the pericardium is affected. All parts of the heart are involved together, but naturally in different degrees; we have to do with a *carditis*, as implying that all parts are affected, rather than any one part, though some one part is likely to be more affected than the others, the processes are such as occur in septic processes elsewhere. If the organisms are comparatively few and less virulent the individual in most cases overcomes the infection and recovers with a scar remaining. There may, however, be perivascular swellings of greater or less degree with inflammatory effusions of various amount and even abscesses. The subsequent course of these lesions is such as occurs in any other organ; there must be a great variety of lesions and the action of the heart muscle under the influence of these lesions must vary: As to this point, Lewis, than whom I suppose there is no greater authority on the subject, explains the occurrence of partial heart block of short duration in acute cases as due to inflammatory swellings which compress the auriculoventricular bundle. In some cases where perhaps an important nutritive vessel is blocked, a degenerative process will have been started which goes on to a fatal termination; or the exudation in the valve goes through the changes which we usually think of in connection with valvular disease; or the toxemia accompanying such septic process may disturb the muscular action.

The signs and symptoms of the disease process will be influenced by the particlar part of the heart affected, by the amount and character of the swellings and exudations, and by their persistence and the changes which they bring about. Thus as regards the pericardium there may be a small area of congestion only, giving perhaps a friction sound of short duration, or at the other extreme there may be an immense exudation, which in itself will cause embarrassment to the thoracic conditions and last over a long time; there is quite surely at the same time infection of the myocardium and probably of the endocardium. These conditions are just such as we find in other organs from septic processes. To grasp this idea of a general cardiac infection is the important thing, and to drop absolutely the idea that what we have been accustomed to call rheumatism, a something due to improper diet, or exposure alone can be accountable for such a definite septic condition.

When one goes back over the ground with this idea in mind, one readily understands how so many children have become the victims of such a septic process. A more or less virulent organism may be absorbed from a post nasal inflammation or a tonsillitis. The resistance, perhaps affected by fatigue, exposure, or what not, is lowered and infection occurs. A large number of children having by inheritance a deficient dental development are so improperly fed that their buccal secretions destroy their teeth and these injure the gums so that they become a fertile soil for organisms, which are readily absorbed by the vascular tissues. These are conditions which are universal, and if the organism happens to be one with an affinity for the heart, or if there is a diminished resistance, a cardiac infection may easily result.

These facts give us a great opportunity for prophylaxis and treatment, and as a matter of years of experience we have found at St. Mary's that about the most important thing we can do for the children with infections (and also without them), is to literally clear out and clean up their nasopharynges, and especially their simply rotten teeth, their gums and mouths. If the supply of organisms can be cut off, just as happens in other forms of sepsis, most individuals will take care of the infection and overcome the attending toxemia and practically recover, though in many instances with a scar, which probably means a heart murmur, or if the auriculoventricular bundle is affected, a partial or complete heart block.

The latest conduct of hearts with such scars, or embarrassment by effusions or exudations, is quite a different question and perhaps such as we all have been accustomed to think of; but I am convinced that little of the older teaching concerning the pathology of acute cardiac processes has been correct. For some extraordinary reason we have satisfied our minds by using the term rheumatism as the cause of heart disease. We must learn that what we have called rheumatism is a form of sepsis, and that this is as applicable to the joints as to the heart. When we adjust our minds to accept the knowledge of the infectious character of these conditions, and allow this knowledge to guide our actions in the way of treatment, and regard the removal of the sources of the infections as the most important thing, we shall have made a great advance.

*Summary.*—The points which I have had in mind to make clear, in this paper, are: (1) That acute cardiac affections are due to germ infections; a sepsis (according to Rosenow the most common infecting germ is *Streptococcus viridans*); (2) that the infecting germs are distributed throughout all the structures of the heart and by the blood vessels of the coronary system; and (3) that the most important factor in treatment is the discovery of the source of infection and its removal.

---

## TECHNIQUE IN RADIOTHERAPY, WITH ESPECIAL REFERENCE TO DEEP THERAPY AS PRACTISED AT FREIBURG BY KRÖNIG AND GAUSS.*

By ARTHUR F. HOLDING, M.D.,

NEW YORK.

It may surprise even roentgenologists to know that a review of the medical literature from 1896 to 1909 shows a total of 3,134 cases of malignant conditions treated by the *x*-ray, the results of which were published. (This does not include cases of non-malignant skin diseases.) Most of these cases were reported as either cured or improved. How many bad, indifferent or good results of *x*-ray therapy remain unpublished nobody knows.

A review of the literature[2] presents the following significant results obtained by the use of Roentgen rays in some gynecological conditions, and particularly in cases of myoma, metrorrhagia, and menorrhagia.

*Read before the American Roentgen Ray Society, Boston, October 3, 1913.

| Myoma | | |
|---|---|---|
| Number of cases treated | 794 | |
| Number of cases still under treatment | 60 | |
| Number of cases which continued treatment | 27 | |
| Number of cases lost track of | 40 | |
| | 127 | |
| Number of cases treated in which results are known | 667 | |
| Number of cases cured | | 376 or 56. 2% |
| Number of cases improved | | 208 or 31. 1% |
| Number of cases unimproved | | 74 or 11. 1% |
| Number of cases relapsed | | 7 or 1. 0% |
| Number of cases dead | | 2 or 0.29% |
| Number of cases which developed an X-Ray erythema | | 52 or 7. 8% |

| Metritis, Endometritis, Menorrhagia or Menopause | | |
|---|---|---|
| Number of cases treated | 353 | |
| Number of cases still under treatment | 39 | |
| Number of cases which discontinued treatment | 33 | |
| Number of cases lost track of | 10 | |
| | 82 | |
| Number of cases treated in which results are known | 271 | |
| Number of cases healed | | 127 or 46. 8% |
| Number of cases improved | | 111 or 41. 0% |
| Number of cases unimproved | | 28 or 10. 3% |
| Number of cases relapsed | | 4 or 1. 5% |
| Number of cases dead | | 1 or 0. 4% |
| Number of cases which developed an X-Ray erythema | | 11 or 4. 1% |

A study of the indications and contraindications,[1] as deduced from the literature on the subject, shows that:

(1) Roentgen treatment is indicated in
  (a) all cases of myoma in elderly patients, particularly
    if the size of the tumor is stationary;
    if there is no bleeding;
    if the tumor does not cause kidney or heart blockade;
    if the tumor does not crowd the pelvis.
  (b) cases of myoma, if the patient is deeply anemic, diabetic, nephritic, bronchitic, arteriosclerotic, or possessed of a bad heart or large thyroid.
(2) Roentgen treatment is contraindicated in
  (a) large, rapidly growing tumors;
  (b) all submucous polypoid growths;
  (c) adenomyomata;
  (d) infected or degenerating cases, or those suspected of malignancy;
  (e) cases of women below forty years with free bleeding and rapid development of the tumor.

From premises based on the large number of cases reported, it is only logical to conclude that Roentgenotherapy is an established factor in scientific medical procedure, and cannot be ignored nor discredited by real leaders of the medical world. It is noteworthy that the number of good results obtained varies directly with the attention given to technique.

One of the most important advances in the technique of scientific Roentgenotherapy was the measurement of the erythema dose. This was followed by the administration of massive doses usually at single sittings. The next improvement in technique was aimed at the generation of an increased number of hard, penetrating rays producing a maximum effect on deep tissues and a minimum effect on the skin. The most notable developments of this later step in technique has been perfected in the Gynecological Clinic of the University of Freiburg, by Krönig and Gauss, in connection with the treatment of myomata and allied gynecological conditions.

Beginning in 1906 Krönig and Gauss started treating selected gynecological cases with the Roentgen rays, giving three treatments per week, with a medium hard tube, at 15 cm. focus—skin distance, filtering through a kolpeurynter, using 2-3 m.a. of current through the tube, each treatment lasting five minutes. Subsequently the rays were filtered according to the method of Perthes, and an attempt was made to utilize the homogeneous rays of Dessauer.

Twenty-five cases were treated by the Albers-Schoenburg technique, consisting of a full pastille dose given in three sittings, using a tube reading 6-8 Walter; focus skin distance, 38 cm.; each sitting lasting about six minutes; 3-5 m.a. passing through the tube; each series of treatments being followed by an interval of fourteen days before a second series of treatments was begun. The skin over the

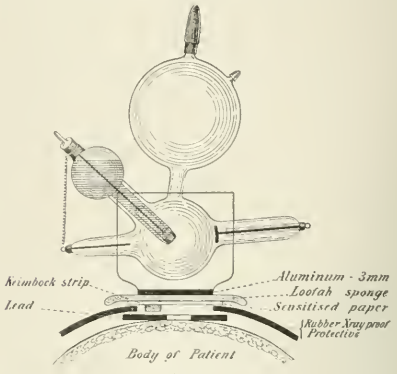

Fig. 1.

area treated was compressed and the *x*-rays were filtered through a layer of aluminum or tin.

Results were obtained by these methods but the patients' treatments extended over three to five months. In order to shorten this period of treatment, extensive experiments were carried out to utilize the greatest number of deep pentrating rays without bad effect on the skin. It was found that by using filters of aluminum 3 mm. thick, with a layer of leather or a layer of sensitized paper, with tubes reading Walter 6-8, a given area of skin could receive twice the usual erythema dose without danger. By treating only a small area of the skin at a time and "cross-firing" the rays so that they were directed toward the seat of the pathological process, and by allowing only a given area of skin to be rayed once, Gauss has administered

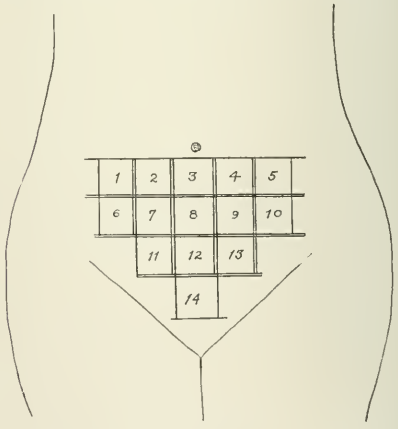

Fig. 2.—Outlines of skin areas treated, permitting "cross-firing" of the rays. Note narrow lanes of untreated skin between square areas treated.

150 to 230 erythema doses to a single case without any ill effect on the skin and with decided therapeutic effect on the tumor.

A series of treatments lasts not less than three hours. To illustrate the program of treatment, I

give a synopsis of two cases selected from the last ten cases in the monograph by Krönig, Gauss and Lembke:[4]

Case 196 (which received the maximum dosage in the series) —Diagnosis:—Myoma of the uterus, tumor extending above the umbilicus.

| | | Days |
|---|---|---|
| Series 1—366 Kienbock units (X) administered in two successive days | | 2 |
| Interval— | | 18 |
| Series 2—549 X, administered in one day | | 1 |
| Interval— | | 20 |
| Series 3—331 X, administered in two days | | 2 |
| Interval— | | 20 |
| Series 4—322 X, administered in two days | | 2 |
| Interval— | | 18 |
| Series 5—321 X, administered in two days | | 2 |
| Interval— | | 22 |
| Series 6—392 X, administered in one day | | 1 |
| Total..2281 X | Period of time under treatment.. | 108 |

Case 197—Diagnosis:—Myoma extending within three finger-breadths of the umbilicus.

| | | |
|---|---|---|
| Series 1—330 X, administered in three successive days. | | 3 |
| Interval— | | 18 |
| Series 2—368 X, administered in one day | | 1 |
| Interval— | | 28 |
| Series 3—234 X, administered in two days | | 2 |
| Interval— | | 17 |
| Series 4—146 X, administered in two days | | 1 |
| Interval— | | 18 |
| Series 5—152 X, administered in two days | | 1 |
| Total..1230 X | Period of time under treatment.. | 89 |

The arrangement of the patient in relation to the tube and the areas of the skin treated are illustrated in Figs. 1 and 2. When using a 220-volt current, 10 to 15 x can be administered to a given area of skin in 6 to 7 minutes; when using 110-volt current, in 7 to 8 minutes; so that if treatment is administered over twenty-one skin areas, the total time consumed, allowing for no interruptions or delays, will last 3½ hours.

In order to be able to administer such protracted treatments as well as to take advantage of the fact that there are a greater number of deep penetrating rays when the tube first lights up, a device for rhythmically interrupting the current to the tube (the rhythmeur is employed). A double bulbed, water-cooled tube with constantly circulating water is used. An air insulated induction coil which has in addition to the usual outfit, condensers and a rhythmeur, is recommended also.

The advantages claimed for the Freiburg technique are: (1) Results obtained in the shortest possible time, (2) utilization of a greatly increased amount of *x*-rays, (3) without danger to the skin.

Krönig and Gauss have reported favorable results in carcinomas of the face, breast, rectum, and uterus. Ashoff, Krönig, and Gauss[5] have reported a series of twenty-five abdominal cases in which exploratory laparotomies proved to be inoperable carcinomata of the abdominal or pelvic organs. Histological sections were obtained, and limited areas of the lesions were rigorously treated. At necropsy sections were taken from these rayed areas. These sections showed marked carcinomatous degeneration or absence of the carcinoma elements and their replacement by connective tissue.

Bumm and Voight[6] have reported thirteen cases of carcinoma of the cervix and four cases of carcinoma of the vulva and vagina that were treated by deep Roentgenotherapy, in combination with mesothorium. These cases were all inoperable, and were so favorably influenced by the treatment that they became operable with good results. The cases received from 62 to 10,000 x of Roentgen rays, and from 6,200 to 25,540 mg. hrs. of mesothorium, treatments lasting from 19 to 84 days. A noticeable tendency in the series of cases reported is to increase the mesothorium treatments and diminish the amount of *x*-rays used.

While there will undoubtedly be more or less dispute not only as to whether *x*-rays shall become the method of preference for the treatment of selected gynecological cases, but also as to whether the three to five hour treatments of the Freiburg technique have sufficient advantages over the simpler methods which have given good results in the hands of such men as Albers-Schoenburg, Pfahler, Stern and many others, we are certainly indebted to Krönig and Gauss for having called our attention to several important details or adjuvants to Roentgen therapeutic technique.

The utilization of the Freiburg technique for inoperable malignant conditions is, perhaps, more important to the development of Roentgen technique than its use in gynecological conditions. Certainly it will meet with an immediate and cordial welcome in this field, where it is sorely needed. Its application to gynecological conditions will be determined largely by the attitude of the gynecologists toward it. The duration of the treatments would seem to be needlessly tedious. They could be greatly shortened by increasing the size of the areas of the skin treated at one time, and although this would not result in such a grand total of figures at the end of the treatment, I venture to predict that the results would be quite as good. However, results are the only arguments admissible.

The fractional, *unmeasured* *x*-ray treatment technique should be unsparingly condemned. The widespread treatment of disease throughout the world, applied by men who do not measure their *x*-rays and are not careful in regard to their therapeutic technique, especially when such men are stimulated by the brilliant results and enormous dosages published by Krönig and Gauss, can only result in a new era of *x*-ray disasters and will tend to further discredit the Roentgen method of therapy. The only way to avoid this, and to safeguard our patients as well as our specialty is to insist that the technique be carefully followed out and that no area of skin be given more than an erythema unfiltered, and not more than 1½ times the erythema dose with the rays filtered through at least 3 mm. of aluminum. It would also be wise when possible to dehematize the skin by compression during the treatment.

In conclusion, let me emphasize that the slogan of success in Roentgen therapy is the same as that of surgery or any other specialty—*technique*.

## A CONSIDERATION OF OBJECTIONS TO PSYCHANALYSIS

By SAMUEL A. TANNENBAUM, M.D.,
NEW YORK.

In the MEDICAL RECORD of September 6, 1913, there appeared an essay entitled "The Psychoanalytic Delusion" which was intended "for the installation of the Psychoanalytic Society a few years ago," which the author had just completed. The writer of the essay is Dr. J. V. Haberman, and the object of the same is to demolish the victims of a very fatal malady—Freudism—that had its origin in the cracked brain of Sigmund Freud of Vienna, a victim of "mental stridulus," to rescue the medical profession and the suffering public from "specious guides" and to "stifle the *ecce!* of the soothsayers too utterly unmitigated for credence!" My reason for replying to this unscientific and pseudo-witty attack on psychanalysis is the fear that upon the unknowing and uncritical reader the quotations from writings of certain neurologists and pediatrists may make an impression which will hinder the spread of the Freudian teachings. A Mona Lisa smile is not the best answer to a scoffer.

The writer asks us to remember that "the Freudian theories all in all have not been accepted by a single distinguished neurologist, psychiatrist, or psychologist in Europe (Bleuler and Jung being the only exceptions), nor by a single professor or individual on the teaching staff of any university abroad." Let us note first the significance of the phrases "in Europe" and "on the teaching staff." American neurologists are of course poor trash unworthy of consideration, lame in judgment and faculty, afflicted with mental stridulus. Putnam, Adolph Meyer, A. Hoch, Jones, Jelliffe, White, and others on this side of the Atlantic, are not fit to pass upon a scientific question in their own specialty. American physicians must feel highly complimented by this tribute to American medicine. That Americans are too fair-minded and too level-headed to reject a theory merely because it is new and because a lot of biased and hopelessly prejudiced European pedagogues refuse to give it earnest consideration or to investigate it seems not to have occurred to the author.

But is it a fact that "not a single distinguished neurologist," etc., accepts "the Freudian theories?" Is not Dr. Haberman here indulging "in terms elastic" and "vocalizing in superlatives?" Of course, it would be absurd to attempt an enumeration of every European instructor and professor who accepts Freud's teachings, and I content myself with referring the reader to any of the following journals (*Zentralblatt für Psychoanalyse, Jahrbuch für Psychoanalytische Forschungen, Internationale Zeitschrift für Ärztliche Psychoanalyse*, and *Imago*) to prove that our friend is misstating the facts. The enumeration of a dozen or two of European professors and instructors would—and should—prove nothing, any more than an array of opposing names, more or less well known (most of them less), prove anything. Fortunately professors and instructors have no monopoly of science, and most of them are not even particularly gifted in their own specialty. From time immemorial your ordinary professor and instructor has been known for his vanity, jealousy, pedantry, unprogressiveness, and narrow-mindedness. We are also told that "in French literature one can find but scant reference to Freud" and that Déjerine devotes only a footnote to his teachings. In reply to this we say that Professor Morichau-Beauchant of l'École de Médecine de Poitiers is a confirmed psychanalyst; there is, therefore, at least one European professor—although only a French one—who accepts Freud's teachings.

On p. 426 the author gives a list of forty-four neurologists and psychologists (not all professors or instructors) who are "opposed to the teachings of Freud." "Opposed" is a good word, a very good word. And why are these good men "opposed" to a theory and method which have proved of incalculable value to numerous patients and which find acceptance and corroboration by earnest and impartial investigators throughout the civilized world? Some, I grant, do not accept psychanalysis because they do not find the evidence sufficient. To these we say: investigate! But, alas, many refuse to investigate for fear that they'll find it all too true, and then what is to become of their own pet theories? Moll has a theory of his own to champion; then how can he accept Freud's? Babinski has a theory of his own; how can he accept Freud's? Dubois has a theory of his own; how can he accept Freud's? Dercum has a dream theory of his own; how can he accept Freud's? Binswanger has a theory of his own to champion and how can he be expected to accept Freud's? And so on. And then, too, we must not forget that some persons, especially psychologists and neurologists, are psychically blind; that is why they take to psychology—to compensate for their natural shortcoming. Nor are leading neurologists particularly distinguished for logical thinking. Isserlin and Kronfeld are referred to as having written masterly essays against psychanalysis; but let any unprejudiced reader read Beuler's analysis of Isserlin's arguments and Rosenstein's analysis of Kronfeld and he will be convinced that neither Isserlin nor Kronfeld is competent to express an opinion of any value on the subject, that they are both helplessly prejudiced, that they do not understand what they are criticizing, that they have not mastered the theory and had no practical experience with the method.

Moreover, it is almost a law of nature that "masters" shall object to innovations (neophobia). There never was a great discovery but it was opposed by the masters. The masters are too thoroughly grounded in the old, too confirmed in error, to be capable of assimilating the new; they are like the mole that has burrowed in the dark so long that it is blinded by the glorious sunlight.

It is objected to psychanalysis that not all cases treated by this method are cured. But this surely in no way controverts the theory or calls the method in question. Quinine does not cure all cases of malaria, arsenic all cases of psoriarsis, diphtheria antitoxin all cases of diphtheria, mercury all cases of syphilis, etc. Hypnotism and suggestion do not cure all cases of hysteria; yet no one would relegate them to the lumber-pile. Some cases cannot be cured by any method of treatment. And, furthermore, is not an occasional failure amply compensated for by the knowledge that by psychanalysis certain cases can be cured which are incurable by any other method? (As to this see my quotation from Bleuler in an essay, "Objections to Psychanalysis Considered," in the *Medical Review of Reviews*, Sept., 1912.) Moreover, it must be borne in mind that not every person practicing psychanalysis is expert in the technique and that we must pay

(and the patients, too) for our experience. Dr. A. may cure a patient whom Dr. B. cannot. It is exactly the same with the surgeon: he does not cure all patients whom he operates upon; yet no one therefore impugns surgery. Besides, some patients do not want to recover. A woman who has developed an agoraphobia to insure her husband's fidelity and to secure his solicitous attentions would be a simpleton to permit herself to be cured.

Strumpell and others have laid stress on the fact that they have seen cases in which psychanalysis did harm. What if it did? The same objection was made to the use of diphtheria antitoxin, to the use of salvarsan, to vaccination, to hypnotism, etc., yet these are not rejected therefore. That a patient may be made temporarily worse by the stirring up of his repressed complexes is not denied. Is it any objection to cerebral surgery that a patient may become worse, or even his life be endangered, as the result of an operation for the removal of a foreign body in the brain or for the exploration of the brain in the search for the cause of obscure symptoms? By no means. The end sought justifies the means. Psychanalysis is such an operation, and the repressed complex is the foreign body. That in incompetent hands psychanalysis is capable of harm cannot be denied; even a simple curettage may be so badly done as to cause unutterable misery or even death; an injection of antitoxin incompetently done may cause death. Salvarsan, mercury, quinine, etc., may, even when properly administered, cause serious complications without invalidating their value as specifics. And sometimes even masters fail. How many mastoid operations result in facial paralysis? Yet we do not abolish aural surgery.

The most frequently repeated objection, and one that is always urged with a good deal of bad temper, pertains to the importance that Freudeans attach to the sexual element in the patient's life. Everywhere, they say, you find "only sexual complexes." Assuming that this is so, if it be the truth what reason is there for a scientist to develop an apoplectic rage over it? One might with as much sense object that in every case of malaria we find plasmodium, in every case of diphtheria the Klebs-Loeffler bacillus, in every case of tuberculosis the tubercle bacillus, etc. And did not the masters object, very strenuously and stupidly object, to finding syphilis in every case of locomotor ataxia and infection in every case of puerperal sepsis? The fact is, as unbiased and cautious physicians and neurologists have found, that in every case of hysteria repressed sexual complexes play the chief etiologic role. From this point we will not budge; it is the alpha and omega of the new theory of the psychoneuroses. And considering the vast importance of the sex instinct in the life of the individual and the race it is not at all improbable that an interference with the expression of the sex craving should be followed by a serious disturbance in the individual's health. If faulty nutrition causes an impairment of health, why should not an abnormal vita sexualis do likewise? A priori there can be no logical objection to the Freudean theory and clinical experience brings daily confirmation of its correctness. But our critics are wrong when they aver that we find only sexual complexes. Freud and his disciples repeatedly mention and never lose sight of the fact that other impulses (the ego impulses—ambition, craving for wealth, revengefulness, etc.) also frequently play a part in the symptom formation and disease production.

Dr. Haberman speaks of psychanalysis resolving itself "into a searching and filthy examination into the past sexual life" of the patient. "Everything is but as thinking makes it," says Shakespeare. As conducted by a tactful and scientific physician the investigation of a patient's amatory life is no more superfluous or filthy than an internist's examination of the urine, feces or sputum, or a gynecologist's examination of a woman's genitalia, or a genitourinary specialist's examination of gonorrheal pus. Any physician who entertains such Manichaean views about the sexual is unworthy of his calling and unfit to practise his profession.

Strümpell, Dercum, Moll, Kronfeld, and Mun, are cited to show that many of the sexual traumata narrated by the psychoneurotic patients are "pure inventions," confabulations, the products of a hyperimagination or pathological fantasy. That there is some truth in this I do not for a moment dispute; but it has nothing to do with the question of the truth of psychanalysis. That the patient lied during a psychanalysis, thus violating the first and only condition imposed upon him—to be perfectly truthful and candid in telling whatever comes to his mind —itself requires analysis. Pathological or impulsive lying is as much a disease as a hysterical twitch. From the analysis of my own patients' lies I can avouch that such lying is due to one or more of the following causes: the patients do not want to be cured; they are ashamed to tell what comes to mind and confabulate a substitute for it; the analyst has not overcome their resistances; there is no sympathy or rapport between that particular analyst and that patient, and the patients are psychic exhibitionists and psychic masturbators. The analyst who understands his business can often, almost always, recognize these lies and through them get at the truth. Moreover, the patient soon finds that lying does not pay, does not cure; and he apologizes and tells the truth. The direct or indirect (symbolic) connection between the symptoms and the etiologic trauma is such an intimate and necessary one that a real psychanalyst (not one like Dornbluth) soon detects the lie. And it is almost superfluous to add that not infrequently the patient's account of sexual traumata are corrobated by the testimony of relatives or by other evidence.

Dercum is quoted as follows: "Loewenfeld gives an instance of a patient of Freud who subsequently came into his hands. The woman stated to him that the sexual events which she had related to Freud when under his treatment had never really occurred. She declared that the whole thing had been a piece of pure (!) imagination." But what proof did Loewenfeld have that the woman was not lying to him when she said she lied to Freud? The fact that she left Freud showed that there was no rapport between them, that she did not like him; and perhaps she was "running him down" because she wished to ingratiate herself with her new physician whom she thought hostile to Freud's theories, and perhaps because she owed Freud money. Patients sometimes do those things.

Strenuous objection is made to Freud's delineation of the sexual life of infants and young children. A number of writers are quoted in opposition to the conclusions and opinions expressed in the "Drei Abhandlungen zur Sexualtheorie." Moll is quoted to the effect that "Freud is utterly wrong"; other writers are cited who deny that masturbation is a regular occurrence in infancy. A list of pediatrists is given who show their opposition to Freud's theo-

ries by not even mentioning him in their books or by referring to them as "unmaintainable exaggerations." Well, nothing but keeping our eyes open will settle these questions; and for myself, I can say that in a fairly extensive general practice during fifteen years in the heart of the lower East Side of New York I never saw a child that did not masturbate and that not a boy or girl past the age of puberty whom I question but admits to present and past masturbation. Mothers whose attention has been called to it invariably admit that their children play with the genitalia when they are not watched, and public school teachers have assured me that one of their most serious problems is the children's habit of masturbating in the classroom. Binswanger's statement—if he is correctly quoted—that masturbation is "only a symptom of the degenerative constitutional disposition" is too manifestly absurd. If Binswanger is right, we are all degenerates. It may not be unimportant to call the reader's attention to the fact that Loewenfeld and others whom the author quotes, do not deny that Freud's conclusions may be correct; they assert only that their experiences do not tally with his. As Bleuler says: future observation may show that Freud is right in every statement that he makes, even those as to which he (Bleuler) does not agree with him. Not dicta but observation will tell.

In one breath Freud's opponents exclaim against his attribution of sexual activities to all children and in the next they vociferate that "if the examiner only takes the trouble, sexual child-fantasies and experiences are to be fished out of every mortal's memory" (Scholz) and that it is incorrect to assign to anything so universal an etiological significance in the production of a neurosis. But no one now denies that the Klebs-Loeffler bacillus causes diphtheria because this germ occurs in the throats of many who never develop diphtheria, or that the mosquito is the cause of malaria because many are bitten without developing malaria, or that the tubercle bacillus is the specific cause of tuberculosis because it is found in the lungs of many who do not have the disease, and so forth. Scientific physicians know that several factors enter into the development of a disease: predisposing cause or constitution, exciting cause, adjuvant factor, specific cause, etc. So the infantile sexual furnishes the soil upon which the neurosis develops and serves to determine and shape the symptoms. To say that psychanalysts leave heredity and constitution out of consideration is to say what is not true. And then—what do we *know* about heredity or constitutional predisposition? (Parenthetically, let me here inquire how the statement that sexual experiences can be fished out of every mortal's memory—a statement that out-Freuds Freud—squares with the assertion that our patients' stories are fabrications and the products of suggestion?)

There is one statement in the "Drei Abhandlungen" that particularly arouses the ire of Freud's opponents. It is this: that thumb-sucking, tongue-sucking, etc., of children is a sexual manifestation. Loewenfeld is quoted to the effect that there is "no necessary connection between sucking and sexual satisfaction." Freud does not claim that there is a "necessary connection" between pleasure-sucking and sexual satisfaction, but that there is such a connection in fact. Let it be borne in mind, in the first place, that Freud was not the first one to assert that children derive a pleasurable sensation akin to sexual gratification from thumb-sucking; that was pointed out by a very careful clinician as far back as 1879. In the second place let it be remembered that so competent a pediatrist as Professor Holt—who is not a Freudian—regards "wonnesaugen" as a kind of onanism. The reasons for so considering it may be summarized somewhat as follows: (1) many children suck the thumb (or other object) at the same time that they are masturbating; (2) some children frankly admit that if they are permitted to suck the thumb they won't pull or squeeze the genitalia (cf. Clark and Atwood, "Habit Movements in Mental Defectives," *Journal of the American Medical Association*, March 23, 1912); (3) some children begin to suck the thumb when they stop masturbating; (4) older children and adolescents practise thumb-sucking secretly; (5) hysterics and others admit that the sucking often terminates with an orgasm; (6) children are frequently seen to break into profuse perspiration and to become exhausted after thumb-sucking just as after masturbation.

An excellent illustration of the method of the anti-Freudians to bring psychanalysis into contempt is the statement that "we are told that little children retain (hold back) their excrement in order to procure themselves a sexual pleasure-profit." But Dr. Haberman omits to say that the child does not do this voluntarily and consciously, that it is a passive and unconscious process. The experience of many observers shows that the passage of hardened feces is frequently accompanied by a pleasurable sensation both in the anal region and in the urethra. And when one bears in mind the facts of pederasty and anal masturbation, it is next to impossible not to attribute an erotogenic function to the lower end of the rectal mucous membrane. Other factors too, *e.g.* exhibitionism, are involved in the unconscious formation during infancy of the habit of constipation.

But, says the author, "no psychologist abroad or in America has accepted Freud's view nor indeed believes, for the most part, in the subconscious at all." In the first place, Freud and those of his followers who understand him, know no "subconscious" and are careful to distinguish between the conscious and the "unconscious." In the next place, Freud did not invent the unconscious. In the third place, it is not true that no psychologist believes in the existence of unconscious psychic activities. As a matter of fact the psychologists who accept the theory of unconscious psychic activities are decidedly in the majority. In the fourth place, it must be borne in mind that the theory of the unconscious is based on the careful observation of numerous facts which cannot be rationally accounted for by any other hypothesis; that the theory is just as sound a logical deduction as Darwin's theory of the origin of species, or as the theory of the atomic constitution of matter, or as the theory of the existence of the universal ether. The theory *explains* facts which can be explained in no other way, and a better theory has never been offered. What these facts are can be found in most of the recent good works on psychology (cf. my essay previously mentioned).

Dr. Haberman makes much of the fact that "nowhere are careful case studies presented, nowhere an endeavor made to substantiate with real evidence." And then he adds the following: "In the way of authorities these writers for the most part refer to one another even though none is recognized as an authority in anything, and the majority could

have had but limited neurological experience." But careful case studies have been published in the German periodicals (in the *Jahrbuch fuer Psychoanalytische Forschungen,* in the *Zentralblatt fuer Psychoanalyse*) and elsewhere, and cases have been reported in English by Brill, Coriat, Putnam, Campbell, Frink, and others. If the author means that no full reports are published in English he knows that this is impossible for three several reasons, any one of which would be sufficient: (1) the analyses usually last so long that the amount of material is too much for publication; (2) the cases are so recent that a full report would lead to the recognition of the patient by his acquaintances; (3) the kind of material elicited in almost all cases is such that publishers would not risk their publication for fear of offending our hypocritical morality. It may interest physicians to know that the *Journal of the American Medical Association* has hitherto refused to publish a single paper on psychanalysis.

Dr. Haberman refers to several writers who cry out against the danger of submitting children to psychanalysis; but be it noted that not one of these masters (Peritz, Vose, Redlich) refers to actual cases coming under their observation. They condemn psychanalysis not for what harm they know it has done but for what they pretend to fear it may do, thus putting themselves exactly in the position of Brutus (also a theorizer) who vilely assassinated Cæsar not for what he was but for what he might become—and who thus made himself the fool of time.

The author says: "In the way of authorities these writers for the most part refer to one another even though none is recognized as an authority in anything." In reply I would say that the leading psychanalysts were recognized neurologists before they became convinced of the truth of Freud's teachings. Let me name a few of these: Bleuler, Jung, Ferenczi, Stekel, Adler, Marcinowski, Juliusburger, Loewenfeld, Hitschmann, Hoch, Jones, Putnam, Jelliffe, Clarke, Brill, Coriat, Onuf, Riklin, etc. And it is not without significance that almost every one of the American psychanalysts, including the writer, took up the subject as an opponent. And then, to whose writings should the psychanalysts refer? To those of our opponents? An astronomer will not cite as a witness one who has never looked through a telescope; a physicist will not learn the composition of the stars from one who has never handled a spectroscope; a mathematician will not leave the solution of a difficult problem to one ignorant of the multiplication table, etc. So the psychanalyst can refer only to those who understand the theory and are skilled in the technique.

As to the assertion that European neurologists and psychologists reject Freud's theories let me say that even if they did, it would prove nothing. The history of Lister is not so old but many can remember the ridicule heaped upon him by his European confreres for maintaining the absurd thesis that living organisms of microscopic size were the cause of "blood poisoning." It was too ridiculous for rational men to discuss! Notwithstanding the misrepresentation and the burlesquing of psychanalysis (did not Tolstoy burlesque "King Lear"?) by those who know no touch of it, the new psychology brings health to a vast army of neurotics and finds new adherents each week the world over. And, "to put it briefly and pleasantly," *le present est gros de l'avenir.*

243 Seventh Street.

## THE VALUE OF ABSORPTION METHODS IN THE WASSERMANN TEST.

By Miriam P. Olmstead, A.M.,

New York.

Research Laboratory of the Department of Health.

The presence of antisheep amboceptor in human serum has been considered by various serologists a source of error in the Wassermann test. The amount of serum used in the test may contain from zero to twenty units and the excess of amboceptor thus introduced may result in such an increase in hemolysis that a positive reaction is lost. According to Bailey[1] from five to fifteen extra units may cause a false negative. Instead of further increasing the excess by the addition of the regulation two units of amboceptor in the course of the test, the natural amboceptor content of the serum may be depended upon for hemolytic action, as in the Bauer modification."[2] Since, however, the amount of natural amboceptor is a variable quantity there is no certainty of the hemolytic system being in balance and the reaction may still be inaccurate. A more satisfactory solution of the problem is the absorption of the natural amboceptor from the serum, so that the balance of the hemolytic system may be assured by the addition of a known quantity of amboceptor. Methods of absorption have been described by Rossi,[3] Jacobaeus,[4] Mintz,[5] and others.

Other serum components as well as natural amboceptor may interfere with a positive reaction. Wechselmann[6] has called attention to the presence in heated serum of complementoids, which, though they have no hemolytic action, retain haptophore groups, hence are capable of being bound by the antigen-antibody combination and prevent the latter from binding complement, which is thus left free to hemolyze the cells subsequently added.[7] Noguchi[8] and others have expressed doubt as to the complementoid nature of the serum components, thus preventing a positive reaction, but agree that the accuracy of the test is increased by their absorption, which may be accomplished by treating the serum with barium sulphate. According to Jacobaeus[4] complementoids, as well as natural amboceptor, may be absorbed by digestion with sheep cells.

In order to determine the value of absorption methods in routine Wassermann work two series of tests were carried out at this laboratory, which, though too brief to be conclusive, are suggestive.

*Series* 1.—The technique employed in this series was the classical Wassermann[9] with the exception of the size, the quantities being proportionately the same, but the final volume 0.5 c.c. instead of 5 c.c. The first incubation was in the water bath at 37° C. for half an hour, the second, after the addition of 0.1 c.c. of 5 per cent. sheep cell suspension and two units of amboceptor, in the water bath for one hour. The tests were then allowed to stand in the ice box over night before being read. A test was considered positive if 0.02 c.c. of serum fixed complement completely, though 0.01 c.c. might show no fixation.

One hundred and sixty-two specimens of serum were tested for natural antisheep amboceptor as follows: 0.02 c.c. of inactive serum, 0.1 c.c. of 10 per cent. complement, 0.1 c.c. of 5 per cent. sheep cell suspension and 0.28 c.c. of physiological salt solution were mixed and incubated in the water bath at 37° C. for one hour. Hemolysis, partial or complete, indicated the presence of natural anti-

sheep amboceptor in seventy-seven specimens, 47½ per cent. The sera that were tested for natural amboceptor after absorption had no hemolytic effect on sheep cells. The natural amboceptor was absorbed according to Rossi's method,[9] *i.e.* three parts of inactive serum and one part of closely packed, washed sheep cells were mixed, kept on ice for from twenty to thirty minutes and then quickly centrifuged. The supernatant serum was tested as usual. Of forty-seven specimens that gave a negative Wassermann reaction before absorption five, 10.6 per cent., were positive after absorption. Two were from undoubtedly specific, active cases, one was from a case of latent syphilis and two were from cases that gave a suspicious history. Five cases with no luetic history remained negative after absorption.

Wechselmann[11] has recommended treating all sera to be tested for syphilis with barium sulphate, to absorb the complementoids and thus increase the binding of complement. The technique of the absorption is as follows: Nine parts of inactive serum, thirty parts of physiological salt solution and five parts of a 7 per cent. suspension of freshly precipitated barium sulphate are shaken together, incubated for one hour at 37° C. and centrifuged. Of the supernatant fluid ten times the regular amount for the Wassermann test must be used. Wechselmann,[11] Wolff,[12] and others have emphasized the non-suitability of commercial barium sulphate for absorption purposes; but they have not stated how fresh a precipitate should be used. We have found a precipitate four weeks old as effective as a perfectly fresh one. Since, however, a suspension of the barium sulphate is apt to become anticomplementary in three or four weeks it is advisable to make up a fresh suspension at least once in two weeks. A simple method of precipitating barium sulphate is described by Wolff.[12] Mix 15 c.c. of sodium sulphate and 10 c.c. of barium chloride. Centrifuge after precipitation has taken place, draw off the supernatant fluid and wash the residue, barium sulphate, once in physiological salt solution. After centrifugalization suspend the barium sulphate sediment in 25 c.c. of physiological salt solution, which makes the proper dilution for use in absorption.

We treated with barium sulphate forty-three specimens that had given a negative reaction in the unmodified Wassermann test, six of which—a percentage of 13.9—gave a positive reaction after absorption. Five specimens from which a history of syphilis could be absolutely excluded were even more clearly negative after absorption than before. Seven positive sera that were treated with barium sulphate lost no binding power thereby. That barium sulphate itself does not bind complement was controlled in each set of tests by a treated negative serum or by barium sulphate and salt solution alone. Eight specimens with a suspicious gonorrheal history that had given a negative reaction in the unmodified complement fixation test for gonococcal antibodies were treated with barium sulphate, after which two of them reacted positively, suggesting that Wechselmann's absorption method might be of as much value in the serum diagnosis of gonnorrhea as of syphilis.

At the suggestion of Dr. A. McNeil a combination of the Rossi and Wechselmann methods was tried, to determine the effect of absorbing both natural amboceptor and the other serum components that prevent a positive reaction. Sixty-six specimens that had given a negative Wassermann reaction in the unmodified test were treated first with sheep cells and then with barium sulphate; eighteen of them, 27.2 per cent., were positive after absorption. Exactly the same percentage was obtained in similar tests for gonococcal antibodies, three out of eleven negative specimens being made positive by absorption with sheep cells and barium sulphate.

Wolff[12] has emphasized the value of the barium sulphate treatment for the absorption of complement as well as complementoid. He also advises the use of active rather than inactive serum, as heating at 56° C. destroys some antibodies, thus weakening a positive reaction. We treated with barium sulphate twenty-eight specimens of active serum that, inactivated, gave a negative Wassermann reaction. Nine of them, 32.1 per cent., gave a positive reaction after absorption. Although this percentage is higher than in any of the series of tests with inactive serum the use of active serum does not seem to be advisable. Three cases from which a history of syphilis could be absolutely excluded gave a positive reaction and in at least one other instance it seemed highly probable that the binding was nonspecific.* In eleven instances 0.1 c.c. of serum bound more complement than 0.2 c.c. Though this phenomenon was not constant, it occurred so frequently as to render the test unreliable.

Thus it appears that by the application of absorption methods in the Wassermann test the number of positive reactions is increased. Wolff's method of treating active serum with barium sulphate gives the highest percentage, but is not, according to our experience, reliable. The combination of Rossi's and Wechselmann's methods gives a fairly high percentage of positives; and as far as may be judged from the results of our few tests there is no danger of thereby rendering the Wassermann reaction oversensitive. The effect of barium sulphate on sera free from syphilitic and gonococcal antibodies should, however, be tested at length before the use of barium sulphate in the routine serodiagnosis of these venereal diseases is recommended. Rossi's method of absorbing natural amboceptor from the serum to be tested is perfectly safe and its practical value is indicated by this series of tests.

*Series* 2.—After the adoption of a change in the technique of the Wassermann test that resulted in an increase in the number of positive reactions a second series of tests was made to indicate whether or not the natural antisheep amboceptor in human serum might still be a source of error in the diagnosis of syphilis. The readings were made as soon as hemolysis was complete in the antigen control (double the amount of antigen used with the serum) and in the serum control (0.04 c.c., double the maximum amount of serum used with the antigen), instead of after an hour's incubation in the water bath and a night in the ice box, as heretofore. The system of reading was the same as in the previous series of tests.

Of two hundred and twenty-nine sera tested for natural antisheep amboceptor sixty-four, 27.9 per cent., were found to contain one or more units.† Fifty-two of these sixty-four were treated with

*Jacobaeus describes a similar experience.

†By a unit of amboceptor is meant the smallest amount that with 0.1 c.c. of 10 per cent. complement completely hemolyzes 0.1 c.c. of 5 per cent. sheep cell suspension when incubated for one hour in the water bath at 37°C.

packed sheep cells, according to Rossi's method,[9] for the absorption of the amboceptor. In one case serum that fixed complement only partially before absorption gave a + + reaction* after absorption. Of the thirty-seven cases that were negative before absorption thirty-four remained negative and three gave a doubtful reaction after absorption. No negative became positive.

Thus by the absorption of natural antisheep amboceptor from the serum of forty-three doubtful or negative cases the diagnosis was changed in four instances, becoming positive in only one. Twenty-six of these same specimens, untreated, gave positive reactions by ice-box fixation.†

*Conclusions.*—Natural antisheep amboceptor is frequently present in human serum. An excess of amboceptor in the Wassermann test may result in false negative reactions. By the absorption of the natural amboceptor the binding power of some sera is increased, especially if the amboceptor has a long period of time in which to act, as is the case when the second incubation of the test is for one hour and the readings are not made until the following day. If. however, the readings are made as soon as antigen and serum controls are completely hemolyzed an excess of amboceptor makes little difference in the results. Thus the method of reading tests seems to determine the importance of absorbing natural amboceptor.

*0.02 c.c. of serum gave complete fixation, 0.02 c.c. complete hemolysis.

†After the mixture of serum, antigen, complement, and saline the tests were set in the ice box for four hours, then filled with sensitized cells and incubated at 37°C. until readings could be made.

## Medicolegal Notes.

**Privileged Communications.**—In an action for personal injuries resulting in the loss of an eye, it appeared that the plaintiff, a railroad engineer, was taken to a hospital after having been injured. There the physician in attendance informed him that they had no eye specialist, and advised him to have an eye specialist examine his eye. The plaintiff permitted a specialist, obtained by the hospital physician, to examine him in order that he might obtain information as to the extent of his injury. The real purpose of this examination was to obtain information to be used against any claim on the plaintiff's part for damages, and the specialist was really employed and paid for by the defendant. The plaintiff, however, did not know this, but believed that the specialist's services were engaged for his benefit, and as his physician acting with the hospital physician. It was held that the specialist was disqualified to testify over the plaintiff's objection, under the Arizona statute providing that a physician cannot be examined without the consent of his patient as to any communication made by the patient with reference to any physical or supposed physical disease, or any knowledge obtained by a personal examination of the patient unless the patient has himself voluntarily testified with reference to such communications.—Arizona & N. M. Ry. Co. v. Clark, C. C. A., 207 Fed. 817.

**Hypothetical Questions—Basis of Hypothesis.**—Hypothetical questions were propounded to physicians in a will case in the following terms: "If one suffering from pneumonia lay in bed on his back from noon or 1.30 P. M., with his eyes and mouth open, his face purple, his pulse about 145, gasping for breath, paying no attention to anything or any person, except to answer a question when asked, and that condition continues until between 5.30 and 6 o'clock, what would you say?" etc. There was no testimony from anyone who pretended to have been in the presence of the testator all of that period. The testimony of two witnesses showed that they were present only a short portion of the time. It was held that the questions were properly excluded under the rule that the hypothesis stated must be founded on evidence which either proves or disproves, or tends to prove or disprove the same, and that, if the assumed facts are not supported by some evidence tending to establish them, the question is improper and should not be propounded.—In re Burnham's Will, Colorado Court of Appeals, 134 Pac. 254.

**X-Ray Photographs and Expert Testimony.**—In an action for personal injuries *x*-ray pictures had been taken, but were not produced in court, and no demand was made for their production. An expert stated in evidence that he was present when they were taken, saw them taken and developed, and looked at the plates immediately after they were developed. This established their identity and correctness. Then the expert and another physician told what they thought the pictures showed. It was held that this was sufficient, in the absence of a demand for a production of the pictures. The court said that "the doctrine that an ordinary photograph is the best evidence of what it contains should not be applied to *x*-ray pictures. They constitute an exception to the rule concerning ordinary documents and photographs, for the *x*-ray pictures are not, in fact, the best evidence to laymen of what they contain. Generally, they are no evidence at all, signifying nothing whatever, except to the expert. The opinion of the expert is the best evidence of what they contain—the only evidence."—Marion v. B. G. Cook Const. Co., New York Appellate Division, 141 N. Y. Supp. 647.

**"Chiropractics"—Necessity for License—Holding Out.**—In a prosecution for practising without a license it was shown that the defendants professed to be chiropractics maintaining an office, holding themselves out as prepared to treat patients for disease with the purpose of curing and healing them, and that they did so without procuring certificates from the state board of medical examiners. It was held that such proof showed a violation of the Iowa statute prohibiting persons from practising medicine without a license in so far as the defendants devoted themselves to and employed means of curing and healing and alleviating pain without a license. They were, therefore, not prejudiced by an instruction that they might be convicted if the jury found that, without certificates, they did publicly profess to cure or heal, or devoted themselves to and employed means of curing and healing and alleviating pain, though the statute did not make any specific reference to the specific act of devoting one's services to and employing means of curing and healing and alleviating pain. Whether the defendants made a practice of prescribing their treatment for the sick was immaterial if they held themselves out as publicly professing to cure or heal.—State v. Zechman, Iowa Supreme Court, 138 N. W. 387.

**Practising Medicine—Validity and Construction of Statute.**—The Texas medical practice act (Act Thirtieth, Leg. c. 123), which requires one desiring to practise medicine to obtain authority so to do from the State Board of Medical Examiners, is held to be valid since no one has an inalienable right to practise medicine or treat diseases for pay. It does not seek to regulate how any one shall treat diseases, but merely provides that, before any one shall treat, or offer to treat, diseases, he shall show his competency and obtain from the State Board of Medical Examiners authority to practise, and one treating, or offering to treat, without medicine, various diseases for a specific compensation is within the act.—Lewis v. State, Texas Civil Appeals, 155 S. W. 523.

## THE QUESTION OF PASTEURIZED MILK.

THE opinion generally prevailing in this country with regard to pasteurized milk as a food for infants appears to be that when breast feeding for some adequate cause is not available and raw cow's milk cannot be depended upon as free from infection and contamination, the wisest procedure is to pasteurize milk. It is argued that pasteurization properly performed, while destroying the germs of infection, at any rate those of tuberculosis, does not injure the nutritive properties of the milk. In Great Britain as a rule medical men have been more skeptical regarding the harmlessness of the various methods of pasteurization, with the result that pasteurization has not been nearly as much in vogue in that country as on this side of the Atlantic, reliance having been placed largely on boiling the milk. Recently, however, pasteurization has been practised on a wider scale, although by many British authorities the method is regarded with a considerable degree of distrust. A correspondence on the matter was begun in the *Lancet*, January 10, 1914, by Edmund Owen, who voiced his views on what he termed the dangers of sterilized milk, and while disclaiming the possession of any biochemical knowledge of the subject, he declared that by the process milk is changed from a living fluid to a dead one. The writer went on to say that in his opinion sterilization renders cow's milk unsuitable as a food for young children—he was half inclined to say dangerous. Ralph Vincent, who has long been known as a strong opponent of sterilization, in the next number of the *Lancet* made a somewhat exaggerated indictment of cooked milk and incidentally attacked the findings given in the final report of the Royal Commission on Tuberculosis. In the issue of January 24, 1914, Eric Pritchard deprecated the sweeping statements of Vincent and emphatically declared that the vast majority of medical men directly interested in the British Association of Infant Consultations and Schools for Mothers held views diametrically opposed. Pritchard showed by statistics drawn from the large district of Marylebone that since artificial infant feeding had been there conducted by municipal authorities and the local health society by means of boiled milk, both the infant death rate and the tuberculosis rate had been reduced to an astonishing degree. Furthermore, Pritchard pointed out that in America, the home of certified milk, there had arisen among certain enthusiasts an agitation for the pasteurization even of certified milk of the highest grade.

By a coincidence, at the same time that Owen's letter appeared, Philip Mitchell of Edinburgh communicated to the *British Medical Journal* the results of certain experiments carried out by him. These experiments showed that a large proportion, more than 90 per cent., of young children with tuberculous neck glands were infected with the bovine bacillus. He made this discovery the basis of a plea for the wholesale sterilization of milk. Thus it will be observed that a good deal of confusion still exists in Great Britain as to the true situation regarding sterilization of milk. On the one hand there are a large number of medical men who claim that bovine tuberculosis is a negligible quantity in the production of human tuberculosis and that consequently there is no need to sterilize milk. On the other hand, there are a yet larger number who hold that tuberculosis is frequently transmitted by the agency of infected milk, and that therefore, in existing circumstances, milk should be sterilized before it is employed as a food for young children. The conclusions reached by the Royal Commission on Tuberculosis and by investigators such as Mitchell would seem to favor the pasteurization of questionable milk supplies.

However, these points as to the transmissibility of and danger from bovine tuberculosis to the human race do not exhaust the subject. There is another phase which has been scarcely touched upon. In the *British Medical Journal*, January 24, 1914, Clive Rivière published an interesting letter. He did not deny that tuberculosis was prevalent in cows and that it might be transmitted to young children, but he took the stand that as things were now this was not an unmixed evil. Nearly every human being becomes infected with tuberculosis before the age of fifteen and Rivière pointed out that it was a matter of the utmost importance whether a child's first acquaintance was with the bovine or the human strain of this organism, since the first generally led to a mild and recoverable lesion, with protection against further infection, while the latter tended to produce more severe and often rapidly fatal forms of tuberculosis. Rivière inferred from experiments and statistics that immunity against tuberculosis was conferred by an early slight lesion. He also suggested that in the production of such immunity bovine tubercle was safer than human tubercle, and consequently so long as the human bacillus was rife we should look upon the bovine bacillus as a valuable means of protection against infection from human sources. Further, arguing from this standpoint, the safest and most practical method open to us at the present time seemed to be in the use of a well mixed milk. In such milk the bacilli would be well diluted and the danger of massive dosage reduced to a negligible figure. Nevertheless it must not be forgotten that dosage was relative and the resistance to tubercle was at a minimum during the first few months of life. It would appear best, therefore, to sterilize the milk at first and gradually add to it increasing quantities of raw milk until this alone is given.

## RADIOACTIVE THERAPY OF CANCER.

THE present excitement in the United States in regard to the power of radium over cancer, and the impending legislation affecting the ownership of radium ore lands and the distribution of the substance, makes an article by Wätjen (*Deutsche medizinische Wochenschrift*, 1914, No. 1), covering the same subject, of some interest. The author selected a number of inoperable tumors, treating them with both radium and *x*-rays for short periods only. In some of these growths numerous metastases were present. None of the tumors showed retrogression save cancers of the breast. None of the metastases was in the least improved. The poor showing was due no doubt to the short period of treatment and the lateness of the disease. Küpferle has attacked deeply seated tumors, but expects improvement only when the field to be rayed is large and homogeneous; and this is difficult of attainment. Recently his clinic has come into possession of large quantities of radium and mesothorium, so that technical difficulties alone prevent the use of the latter. For the present he is using *x*-rays for deep-seated tumors.

Aschoff believes that intensive *x*-rays do better work than mesothorium, but this is because the rays can attack a large surface at once; but the remote result is not favorable and metastases are not influenced at all. The effects of small doses do not seem to have been studied critically. The author does not say "return to the knife" but give radiotherapy a chance on early, not only on hopeless cases. Oberst holds that radiotherapy in the first stage of cancer can not compete successfully with the knife. We improve the technique greatly but the desired result is as far off as ever. A brilliant cure by radium may be followed by an untimely recurrence. Radiotherapy is of little or no avail in metastases.

In the discussion that followed the reading of these papers Bulius stated that the knife in the first stage gave at least 50 per cent. of cures—a good percentage. Röos was in favor of the knife, followed at once by destruction of all tumor cells through radiation. Schlimpert stated that Bulius's claim of 50 per cent. of cures in the first stage was without statistical basis. If statistics of remote results were accurately stated the knife did not figure to such an extent as had commonly been believed.

## IS LEUCEMIA AN INFECTIOUS DISEASE?

ONE of the vexing problems of pathology is the cause of the various forms of leucemia. The acute type of this disease with its rapid malignant course often beginning with an ulcerative angina, and accompanied by a febrile movement, strongly suggests an acute infection. Experiments to transmit this disease from human beings to animals have failed. No microbic factor has as yet been isolated, although Löwit in 1900 described what he regarded as protozoa in the white blood cells. There are two main theories that attempt to account for the pathological changes in this disease. One of these postulates a chemotactic influence exerted by toxins which cause an increase of lymphocytes in the blood. The other theory regards this cellular proliferation as closely allied to tumor growth. Many arguments have been advanced both in favor of and against each of these hypotheses.

An investigation which seems to indicate an infective origin for leucemia has recently been conducted by V. Ellerman (*Zeitschrift für klinische Medizin*, Vol. 79, Nos. 1 and 2). His observations were confined to the leucemia of fowls. It is impossible to state dogmatically that this disease is identical with the disease as found in human beings. But the similarity between the two is most striking. In both diseases there is a markedly increased leucocyte count with a predominance either of lymphocytes or of myelocytes. There is also in both conditions a hyperplasia of the hemopoietic organs. In both cases there are cellular infiltrations in the liver and kidneys. The disease in the fowl as in the human being is usually chronic and is always fatal.

Ellerman succeeded in transmitting the leucemia of fowls from animal to animal by means of inoculations of cell-free filtrates obtained by passing specimens of blood from affected animals through Berkefeld filters. Healthy fowl inoculated with these cell-free filtrates developed all of the characteristics of the disease. Moreover, the two types of the latter, the lymphatic and the myeloid were differentiated in the fowl as in the human being. Ellerman concludes that the virus of leucemia belongs to the filtrable microorganisms.

Possibly the good effects observed in the treatment of leucemia by means of benzol may be attributed to the antiparasitic action of this substance.

## TRANSMISSION OF OZENA BY DOGS.

PEREZ of Argentina has devoted much time to establishing the nature of this condition. Perhaps to escape the criticism of working in a country remote from the great medical centers, he has done much of his work in Continental laboratories, and hence has been able to make converts among coworkers. Facts regarded by competent authorities as beyond all question are the identity of true ozena and some types of ordinary atrophic rhinitis. The same germ of Perez is found in each. There is, of course, nothing in common between these affections and syphilis, and putrid disease of the nasal sinuses. It has been proved that ozena and atrophic rhinitis are alike infectious. One case in a family presenting the former, while other members show the latter. It has taken years to follow up cases, to prove that an adult with true ozena must have transmitted the disease to a child, several years intervening between the appearance of the second case. Most significant is the fact, proved by Perez and others, that the coccobacillus of Perez is a normal denizen of the dog's nasal chambers; that it may behave pathologically there and even be transmitted to human beings, probably through the nose. Numerous cases of this sort have been recorded, the evidence being far more complete than in any case of transmission from man to man. In the *Berliner klinische Wochenschrift*, Dec. 29, both Perez and Hofer contribute papers on this subject. The latter, who has repeated all of Perez's experiments, appears to be more than satisfied with the outcome. An interesting question is whether from a Perez culture an immune serum can be ob-

tained which will both relieve the disease and at the same time clinch the theory of its origin. Canine ozena should be studied *per se* and as related to human beings.

### "Instructive Mistakes."

Under this heading a number of unsigned case reports appear in each number of the *British Journal of Surgery* and thus far, at least, have justified the adoption of this innovation. Most men are willing enough to record successful cases but hesitate to acknowledge having made serious mistakes. A properly edited series like this, where the author is known to, and his veracity vouched for by, the editor, should be most helpful. Most of us quickly recall some error in diagnosis or in judgment, the recital of which would undoubtedly teach a valuable lesson and allow some other doctor (and patient) to profit by our bitter experience. In a previous editorial we referred to one of these reports which appeared in the October number and was entitled: "Tumour of the left vagus removed in mistake for a fibroma, with fatal result." In the January number we find the following four reports: Duodenal ulcer and ruptured tubal pregnancy, in which the pregnancy was overlooked; Melanotic sarcoma mistaken for an innocent tumor. A grave error in prognosis; An axillary abscess mistaken for a sarcoma; and A sarcoma mistaken for an abscess. These reports are well worth reading and it is safe to predict that the lessons taught will be kept much more firmly in mind from the very fact that one realizes that he is profiting by the actual mistake of another and will be anxious to avoid the error himself should a similar case appear in his own practice. One of these cases shows the danger of relying upon the frozen section for an absolute diagnosis in cases of suspected sarcoma. An unnecessarily extensive operation was done on the strength of the pathologist's report upon the small section that was removed for examination. The case proved to be chronic abscess in the subscapular lymph glands. "The portion on which the wrong diagnosis had been founded consisted of just that mixture of round and spindle cells which *might* indicate a sarcoma." Each of the other cases brings out some equally important and instructive point.

## News of the Week.

**Public Health Service Examination.**—Candidates for admission to the grade of assistant surgeon in the United States Public Health Service will be examined at the Bureau of the Service, 3 B street, S.E., Washington, on Monday, March 9, 1914, at ten o'clock A.M. The examination is open to men between 23 and 32 years of age, graduates of reputable medical colleges, and of good professional and moral character. Candidates must have had one year's hospital or two years' professional work. The examinations are: 1, Physical; 2, Oral; 3, Written; 4, Clinical. Assistant surgeons receive $2,000 yearly, and after four years' service are entitled to examination for promotion to the grade of passed assistant surgeon, the yearly salary then being $2,400. When quarters are not provided commutation at the rate of $30, $40, and $50 a month, according to grade, is allowed. For invitation to appear before the board of examiners, application should be made to the "Surgeon General, Public Health Service, Washington, D. C."

**Civil Service Examination.**—Competitive examinations, open to men and women, for the position of Sanitary Supervisor, New York State Department of Health, will be held in various cities throughout the State on March 7, 1914. Intending competitors must execute application blanks and file them in the office of the Civil Service Commission on or before March 2, 1914. The qualifications of sanitary supervisors are as follows: They must be physicians, not less than 28 or more than 60 years of age, and have been previously engaged in public health work of various sorts; they will not be allowed to practise medicine or engage in any other regular occupation or business; but shall be at liberty to accept or retain other positions in public health work. The salary of the office is $4,000 per annum. Application blanks may be procured by addressing the State Civil Service Commission, Albany, N. Y.

**Examination of Dentists.**—The Surgeon General of the United States Army announces that examinations for the appointment of acting dental surgeons will be held in various places throughout the country on April 13, 1914. Application blanks and full information may be procured by addressing the "Surgeon General, United States Army, Washington." Applicants must be citizens of the United States, between 21 and 27 years of age, graduates of a licensed dental school, and of good moral character and habits. Acting dental surgeons are employed under a three years' contract at the rate of $150 per month, and at the expiration of this time are entitled to examination for promotion to the grade of dental surgeon with the rank of first lieutenant. There are at present twenty-eight vacancies.

**Grant to Dr. McClintock's Widow.**—Two years' salary, amounting to $5,570, was voted by the United States Senate on February 12, to the widow of Dr. Thomas W. McClintock of the United States Public Health Service, who died from spotted fever contracted while he was making researches into the cause and cure of the disease.

**Prof. A. W. Mayo Robson** of London, who is an honorary Fellow of the American Surgical Society, was shot in the thigh recently by a gun bearer while on a hunting trip in British East Africa. He was carried to Nairobi for treatment and is now recovering.

**Dr. Benjamin T. Tilton,** surgeon in chief at St. Mark's Hospital, New York, was the guest of honor at a dinner at Lafayette Hall on February 9. Of the five hundred present two hundred were former patients of Dr. Tilton, and on their behalf a loving cup was presented to the surgeon. At the same time announcement was made that an annex to St. Mark's Hospital, to cost $150,000, would shortly be built on Second avenue.

**An Interesting Decision.**—Justice Marks of the Sixth District Municipal Court of the City of New York recently handed down a decision of interest to physicians. The plaintiff in the case was Dr. Mark J. Schoenberg, a physician of New York, who had sued the estate of Mr. M. E. Bernheimer for services rendered. Mr. Bernheimer and the physician had both been in attendance last September at the Supreme Court in Brooklyn, the former as the defendant of the case then on trial and the latter as a witness, and while the physician was in the witness chair Mr. Bernheimer was

taken ill and fell from his chair unconscious. The physician being excused by the judge hastened to Mr. Bernheimer's side and with another physician present in the court room attempted to revive him. Their efforts were unsuccessful, however, and the patient died inside of half an hour without regaining consciousness. The physician rendered a bill for $500 for his services, and payment was refused by the executors of the estate. Suit was then begun. In his decision Justice Marks reviewed the case, and discussed the question of whether the financial condition of the patient, who in this instance left a large estate, has anything to do with the amount which may properly be charged by the physician, the value of the special services rendered, and the liability of a person who is unconscious or in extremis for services rendered by a physician who has not been called by the patient or his family. After citing a number of previous cases, the judge decided that the physician in this case had the right to recover from the estate and that the charges for a physician's services may properly be based upon the financial condition of the patient. He held, however, that the services rendered in this case were not worth more than fifteen dollars, and rendered judgment for this amount for the plaintiff.

**Pharmacy Case to Supreme Court.**—The New York County Medical Society which is prosecuting Morris Lederman of the Standard Pharmacy Company for practicing medicine without a license, recently reached an agreement with the defendant by which the case will be carried to the Supreme Court for decision as soon as possible. The case involves the interest of a number of pharmacies in the city which, it is alleged, start under a trade name, hire a physician, and give free treatment if the prescriptions given are filled at the pharmacy. Counsel for the Medical Society holds that the law which prohibits a corporation from practicing medicine does not allow an individual to do so under a trade name.

**City Death Rate.**—For the week ending February 7, the death rate in New York City was 14.04 per 1,000, representing a total of 1,503 deaths. For the corresponding week of last year the rate was 15.23 per 1,000 and the total number of deaths 1,568. The following causes showed a decreased mortality: Lobar pneumonia, bronchopneumonia, whooping-cough, diarrheal diseases, Bright's disease and nephritis, diseases of the nervous system, and violence. Viewed from the point of age, the mortality of infants under one year showed a decrease of 16 deaths, that of children under five years a decrease of 46, between the ages of five and sixty-five a decrease of 71, while, on the other hand, among the aged there was an increased mortality of 52 deaths. For the first six weeks of 1914 the death rate was 14.62 per 1,000, as against 14.68 for the same period of 1913.

**Women Qualify as Interns.**—For the first time in the history of the institution two women physicians have successfully passed the examination held at Bellevue Hospital for admission to its interne staff, and the question of their appointment is now before the Board of Trustees. The successful candidates are Dr. Helen Balliser of Brooklyn and Dr. Ana Tjohnlands of New York, both from the Cornell University Medical College. At the close of the examinations, for which there were fifty-five entrants, these two women held tenth and twelfth places respectively.

**German Orthopedic Society.**—The Thirteenth Congress of the German Orthopedic Society will be held on Monday and Tuesday during Easter week, April 13 and 14, in the Langenbeck-Hause, Ziegelstrasse 10-11, Berlin, under the presidency of Prof. Dr. Th. Kölliker. The chief subject for discussion will be "The Operative Treatment of Spondylitis."

**Physicians' Motor Club of Philadelphia.**—At the annual meeting held on January 20, the following officers were elected: *President*, Dr. S. Leon Gans; *First Vice-President*, Dr. William Duffield Robinson; *Second Vice-President*, Dr. John J. Robrecht; *Third Vice-President*, Dr. Charles A. E. Codman; *Secretary*, Dr. Howard A. Sutton; *Treasurer*, Dr. Lewis H. Adler, Jr.; *Directors* (for four years), Dr. H. Augustus Wilson and Dr. Sylvester J. Deehan.

**The National Association for the Study of Epilepsy** will hold its annual meeting in Baltimore, Md., on Monday, May 25, 1914. The programme and details of the meeting will be announced later. Dr. J. F. Munson, Sonyea, N. Y., is the secretary of the association.

**Federation of Medical Boards.**—The second annual session of the Federation of State Medical Boards of the United States will be held at the Congress Hotel, Chicago, on Wednesday, February 25, 1914. The meeting will be called to order promptly at 9 a.m., with President Charles H. Cook in the chair, and papers on the following subjects will be presented: "Public Health Administration," by Surgeon General Rupert Blue, U. S. Public Health Service; "Should the Federation of State Medical Boards of the United States recommend a uniform minimum curriculum for medical schools?" by Dr. John L. Heffron, Dean of the College of Medicine, Syracuse University; "The use of the United States Medical Services in standardizing medical education," by Lieut.-Col. J. R. Kean, Medical Corps, U.S.A.; "Some thoughts on the standardization of medical education," by Dr. Harold C. Ernst, Harvard University; "What instruction ought medical colleges to give in pharmacology?" by Dr. Samuel W. Lambert, Dean of the College of Physicians and Surgeons, Columbia University; "The viewpoint of the State examiner," by Dr. Walter L. Bierring, president of the Iowa Board; "The viewpoint of the pharmacist," by Dr. Bernard Fantus, professor of pharmacology in the University of Illinois; "General discussion of a model medical practice"; "General discussion of credentials and the evil of the 'Equivalent' "; "General discussion of practical examinations"; "Reciprocity," by Dr. John Montgomery Baldy, president of the Pennsylvania Bureau of Medical Education and Licensure. At the business session the reports of officers and committees will be received and officers for the ensuing year will be elected. Further details may be obtained from Dr. Otto V. Huffman, Secretary-Treasurer, Secretary of the New York State Board of Medical Examiners, Albany, N. Y.

**American Life Convention.**—The fourth mid-year meeting of the Medical Section of the American Life Convention will be held at the French Lick Springs Hotel, French Lick, Ind., on March 4, 5, and 6, 1914, with Dr. James H. Stowell of Chicago as chairman. A long and interesting programme has been arranged, the details of which may be obtained from Dr. Stowell.

**New York Society of Anesthetists.**—A regular

meeting of this society will be held at the Academy of Medicine, New York, on Friday evening, February 27. The programme will include papers by Dr. Charles Teter and Dr. William Branower.

**Dr. Alphonse Bertillon,** the noted criminologist and the director of the anthropometric department of the Paris police, died in that city on February 13, in the sixty-first year of his age. Dr. Bertillon was known chiefly as the originator of the system called by his name for the identification of criminals by accurate measurement. The system was first introduced into France in 1883 and rapidly grew in popularity until it was adopted by practically all of the police departments of the larger cities. Of late years, however, it has been somewhat supplanted by the finger print method of identification. In recognition of his work Dr. Bertillon was some time ago made a Chevalier of the Legion of Honor.

**Inwood Hospital Report.**—During 1913 the Hospital and House of Rest for Consumptives at Inwood-on-the-Hudson, N. Y., cared for 133, of whom eighty were admitted during the year, making a total of 4,414 patients treated at the hospital during its forty-five years of existence. Of the 133 patients treated last year, forty-three were discharged and twenty-one died. The daily average of patients under treatment for the year was 65.1. The total number of days' care given was 23,786, an increase of 3,496 over the preceding year. The average stay of each patient was 178.8 days, as against 147.7 for the preceding year. The patients were received from various hospitals, clinics, settlements, and charitable organizations.

**Automobile Death Toll.**—There were 580 persons killed by vehicles in the streets of New York during 1913, according to the report of the National Highways Protective Association, and of these deaths 302 were due to automobiles. Trolley cars killed 108 persons, and wagons, 170. During 1912, the total number of deaths caused by vehicles was 532, and during 1911, 423. The number of killed and injured during 1913 amounted to 1,485, excluding those who received only minor injuries which escaped record.

**Personals.**—Dr. Karl Völckers, professor of diseases of the eye in the Königliche Christian-Albrechts Universität, Kiel, Prussia, and the author of a number of works on ophthalmology, died at Kiel on February 3, aged 77 years.

Medical Inspector William C. Braisted has been appointed by the Secretary of the Navy as Surgeon-General of the United States Navy, relieving Surgeon-General Stokes, whose terms of four years expired on February 6. In making the appointment, Secretary Daniels issued a statement praising the administration of Surgeon General Stokes, and declaring that never before have the standing and reputation of the Medical Corps of the Navy been so high.

Dr. Hermann M. Biggs was the guest of honor at a dinner given by two hundred of his professional colleagues in New York on February 7. Among the speakers were Prof. William H. Welch of Johns Hopkins University, Dr. William H. Park, Mr. Robert W. De Forest, Borough President Marks, and Dr. Biggs himself.

**Phi Delta Epsilon.**—At the annual convention of the Phi Delta Epsilon Fraternity held recently at the Yale Club, New York, the following officers were elected for the ensuing year: *Grand Consul*, Dr. Murray B. Gordon, Brooklyn; *First Vice-Consul*, Dr. Leo S. Schwartz, Brooklyn; *Second Vice-Grand Consul*, Dr. B. B. H. Aarons, Philadelphia; *Third Vice-Grand Consul*, Dr. George Piness, Passaic; *Grand Chancellor*, Dr. Aaron Brown, New York; *Grand Scribe*, Dr. Ellis Campus, New York; *Grand Historian*, Dr. Irving Gray, Brooklyn.

**Medical Society of the Missouri Valley.**—The 26th semi-annual meeting of this society will be held at Lincoln, Neb., on March 26 and 27, 1914, under the presidency of Dr. F. B. Tiffany of Kansas City, Mo.

**Medico-Legal Club of Philadelphia.**—At the annual meeting held on January 27 the following officers were elected for the coming year: *President*, Dr. W. T. Hamilton; *Vice-Presidents*, Dr. E. W. Kelsey and Dr. Benjamin H. Swartz; *Secretary*, Dr. C. W. Schaubel; *Treasurer*, Dr. C. M. D. Peltz.

**Obituary Notes.**—Dr. Alonzo F. Huntoon of Los Angeles, Cal., a graduate of the Missouri Medical College, St. Louis, in 1881, a member of the American Medical Association, the Medical Society of the State of California, and the Los Angeles County Medical Society, and formerly a well known practitioner of Duluth, Mich., died in Los Angeles on February 2, aged 62 years.

Dr. George Lloyd Magruder of Washington, D. C., a graduate of the Georgetown University School of Medicine, Washington, in 1870, and for many years professor of materia medica and therapeutics, and dean of the school, a member of the American Medical Association and the Medical Society of the District of Columbia, and one of the organizers of the Central Dispensary and Emergency Hospital, and a member of the staff of the Providence Hospital, died at the University Hospital, Washington, on January 28, aged 65 years.

Dr. James A. Cox of New York, a graduate of the Long Island College Hospital, Brooklyn, in 1891, died at his home on February 3, aged 55 years.

Dr. Ray Vaughan Pierce of Buffalo, N. Y., a graduate of the Eclectic Medical College, Cincinnati, O., in 1865, died at his winter home on St. Vincent's Island, Fla., on February 4, aged 74 years.

Dr. Armin Ubelacker of Morristown, N. J., a graduate of the New York Homeopathic Medical College and Hospital in 1871 and a member of the American Institute of Homeopathy, died at his home on February 6, following the amputation of his foot at the Memorial Hospital a few days before.

Dr. Daniel C. Logue of Bellmore, L. I., a graduate of the New York Medical College, and said to have been the last survivor of the crew of the *Monitor*, on which he served as surgeon during her engagement with the *Merrimac*, died at his home on February 3, aged 81 years.

Dr. J. Henry Ludwig of Boyertown, Pa., a graduate of the Medico-Chirurgical College of Philadelphia in 1903, and a member of the Medical Society of the State of Pennsylvania and the Berks County Medical Society, died at the Pottsville Hospital, following an operation for appendicitis, on January 31, aged 38 years.

Dr. Luther K. Stine of Philadelphia, a graduate of the Department of Medicine, University of Pennsylvania, in 1860, died at his home, January 23, aged 77 years.

Dr. Caroline H. Vanhorne of Englewood, N. J., a graduate of the Woman's Medical College of Pennsylvania, Philadelphia, in 1894, died at her home, from heart disease, on February 3, aged 51 years.

## Obituary.

### ROSWELL PARK, M.D.,

BUFFALO, N. Y.

Dr. Roswell Park, Professor of Surgery in the University of Buffalo, died suddenly at his home in that city on February 15. Born in Pomfret, Conn., May 4, 1852, he received his medical degree from Northwestern University in 1876. He was successively Demonstrator of Anatomy in the Women's Medical College, Chicago, Adjunct Professor of Anatomy in the latter institution, and Professor of Surgery in Rush Medical College, and in the Medical Department of Northwestern University. In 1883 he was appointed Professor of Surgery in the University of Buffalo and Surgeon to the Buffalo General Hospital and held these positions to the time of his death. He was a director of the New York State Cancer Laboratory at Buffalo. Dr. Park received honorary degrees from Lake Forest University, Harvard, and Yale. He was at one time President of the American Surgical Association and of the Medical Society of the State of New York. He was the author of many medical works, notable among which are his: "Modern Surgery" and "A History of Medicine." He was associate editor of *The Annals of Surgery*. In the death of Dr. Park this country has lost one of its most distinguished surgeons and scholars.

### OUR LONDON LETTER

(From Our Regular Correspondent.)

HORMONES—GRESHAM LECTURES 3 AND 4—PITTSDOWN SKULL — RECONSTRUCTION OF SKULLS — PUBLIC HEALTH—INSURANCE NOTES—OBITUARY.

London, January 30, 1914.

It is only ten years ago since Professor Starling announced at the Royal College of Physicians his discovery of "hormones" in the secretions of ductless glands, and now we have had a discussion at the Royal Society of Medicine on the therapeutic value of these interesting bodies. This was opened on the 20th inst. by Prof. G. R. Murray, who remarked that our knowledge of them had increased so rapidly that we must beware not to confuse advance with mere theorizing. Hormones regulated metabolism, some controlling or inhibiting, others stimulating. They might be tried in (1) disease or injury of the glands secreting them; (2) the physiological need of increased secretion; (3) when the known action might be of service though there was no deficiency; (4) empirically. Thyroidal hormones had been of value in cretinism and myxœdema for which treatment must be continued with a preparation known to be physiologically active and the dose regulated by the effect on the individual. Simple goitre gave an example under group (2), but care should be taken to exclude Graves' disease. Obesity would be an example under (3), and under (4) rheumatoid arthritis, rickets and nocturnal enuresis. In reference to suprarenal hormones he had not found adrenalin replace them in Addison's disease, though recoveries had been reported, and they were useful in asthma and hemorrhages. Some spoke well of the remedy in Graves' disease, but he had not found it of real use. As to the pituitary gland good results had been claimed for its extract, and it seemed to stimulate the mammary and renal activity, but was of no use in acromegaly. Judgment must be reserved as to ovarian and other extracts and he would not confuse questions arising by referring to combinations of two or more hormones.

Professor Starling said his hormones were chemical messengers by which correlation was maintained between different organs. These correlations he considered as twofold: (1) Acute, where change in organ A was followed quickly by change in one or more organs, the change ceasing in these with cessation in A. In (2), chronic, the changes in all were similar but slower. The balance of effect and cause was brought about by the instability of the hormone. Secretin acted acutely; so did carbonic acid, which took messages to the respiratory and vasomotor centres. Adrenalin wa rapid, was secreted in excess over fright and put the animal in the best state for defense or flight. Hormones were also rapidly destroyed, and this was a difficulty in some cases and rendered them useless by the alimentary tract. Secretin was, therefore, given intravenously and harm might be done if the body was not prepared for it. Much the same was the case with adrenalin. Of chronically acting hormones were the thyroid, pituitary, pancreatic, etc. Their value was based on arguments, for they had no direct proofs, except in the case of the thyroid, and that was slight. His laboratory experiences made him sceptical about extracts, for, with all conditions in his favor for exact experimentation, he had made mistakes. Only as to the thyroid was there direct evidence of therapeutic results—perhaps because that gland was connected originally with the alimentary tract. Dr. Leonard Williams was at first afraid of the pressor action of the pituitary, but had found this was not produced when given by the mouth. He disapproved the term thyroid excess for Graves' disease, the symptoms of which were not such as simple excess produced; in fact, deficient secretion could often be detected. He employed small doses of thyroid extract and calcium (chloride or lactate). Dr. H. H. Dale said extracts of ductless glands could be regarded as drugs. Pituitary extract was tonic to involuntary muscle, acting by increasing the sensitiveness to ordinary stimulants, rather than by itself stimulating it.

Dr. Hale White (presiding) said many people took excess of thyroid extract for myxedema. In a woman affected with that disease and pregnant the thyroid normally enlarged. Would it be right to give more thyroid? In obesity thyroid often started a loss of fat which diet had not done, but would then continue without more thyroid. In asthma he found adrenalin remarkably successful.

In this third Gresham lecture Dr. F. M. Sandwith continued his review of the late Medical Congress, dealing chiefly with the possibilities of radium. The difficulty of investigating rapidly its therapeutic value lay in the small quantities available. Probably its curative properties were vast, but on account of the widespread prevalence of cancer the new agent had been most used for that disease. Passing on to the section of the History of Medicine, the lecturer referred to Mr. Welcome's bacteriological laboratory at Khartoum and his intention to establish others in the tropics. He then proceeded to speak of prehistoric human remains, from the study of which it had been suggested that man's stature and brain were practically the same now as 400,000 years ago. The owner of the Pittsdown skull, he conjectured, might have lived a million

years ago, and even then, if not capable of speech, and still using his teeth for grasping or defense, he could fashion stone implements with considerable skill. The origin of man seemed to recede so far they could hardly reckon it in years, but in the sequence of geological periods. That seems the position of the theorist who thinks the idea of development accounts for everything, even for the beginning of development itself. At his concluding fourth lecture of the series Dr. Sandwith introduced the cinematograph and showed pictures concerned with various biological matters and explained further how by means of a combination of the cinematograph with the microscope it was possible to demonstrate a number of interesting phenomena of cells and microbes.

Professor A. Keith, R. C. S., has also spoken of the Pittsdown skull in his presidential address at the Royal Anthropological Institute. That address was devoted to the "Reconstruction of Fossil Human Skulls." He said when he took up earnestly the study of skulls of extinct forms of mankind he realized, as others had done, that the methods of measurement of complete modern skulls were useless in this study. A complete fossil skull was not obtainable, never would be, and the measurement of parts were insufficient. He set to work to find out a new method of interpretation, and some persons were amused by his theories, and some fancied he had "a bee in his bonnet." When he began to apply his theories to the Pittsdown skull the "fat was in the fire." It was not possible to make a dogmatic assertion on the question, but he declared his conviction that there could be only one way of building up a skull, and he proceeded at the request of friends to build up this according to his method. To test this there had been submitted to him some fragments of a modern Egyptian skull, raising problems similar to those in the Pittsdown case. From them he built one which varied from a cast of the original by only one millimeter in width, two in height, and twenty in total capacity. The only serious mistake he made was in making the forehead too large, as he had assumed it was the skull of a male, whereas it was that of a female. Professor Keith related the nature of the various checks he employed in his system of reconstruction. He wished to show that it was not mere guesswork, but that the reconstruction of skulls was a science which before long would become exact.

The medical officer of the Local Government Board has made a report on the public health in England and Wales during 1912-13. Compared with the average of 1891-1900, the infant mortality rate declined 38 per cent., measles 16 per cent., scarlet fever 66, whooping cough 40, croup and diphtheria 57, enteric 75, tuberculosis (all forms) 32, pulmonary 25 per cent. The death rate from all causes was less by 27 per cent. in 1912 than in the period 1891 to 1900.

Some differences among the Governors and other bodies connected with St. George's Hospital have been much talked about. The Princess Christian resigned the Presidency. It is said that some irregularities of slight importance have taken place, one relating to appointment of a superintendent secretary. The committee and all interested will probably attend the Governors' meeting, which is due on the 12th prox., when the several matters can be explained and discussed.

The Insurance Act still gives rise to much discontent which has extended to the army—not unnaturally, considering how it affects the soldier. When he is ill, *i.e.* in hospital, deductions are made from his pay, but the societies in which he is compulsorily insured contribute nothing toward that deduction. The men say they should be paid, as civilians are, during illness, and the Insurance Commissioners ought to refund to them the hospital deductions.

The Strand General Hospital reports a decrease of contributions by the working classes to the extent of £130 last year, attributing this to people being treated on the panel system who used to voluntarily pay small sums to the hospital.

The Manchester Insurance Committee reports 54,000 medical cards posted under the act have been returned by the "dead letter" office. At Liverpool such "dead" cards have not been counted but weighed. Their weight exceeded 3 cwt.

Dr. Philip Whitcombe has died, aged 98, at Gravesend, where he practised sixty years and held many offices, among them Medical Officer to the Port of London.

Dr. Alexander Newington, physician to Ticehurst Lunatic Asylum, was killed by an accident in driving his motor car on the 17th inst. He was at one time physician's assistant at Bethlehem Hospital, and was a Cambridge M. B.

Brigade Surgeon C. C. Reid, who died in December last, qualified in 1852, and entered the army service the next year. He served in the Crimean War and received the medal with clasp and also the Turkish medal. He was in the Soudan expedition and received the Egyptian medal and clasp as well as the Khedive's bronze star.

## OUR BERLIN LETTER.

(From Our Regular Correspondent.)

RADIOTHERAPY OF CANCER—RADIUM IN THE TREATMENT OF CANCER OF FEMALE GENITAL ORGANS—FAVORABLE AND INJURIOUS EFFECTS—THE LATTER MAY BE DELAYED—RADIUM AND RECURRENCE—EFFECTS OF RADIUM ON GLANDS AND ON METASTASES—INFLUENCE OF AGE OF PATIENT—QUESTION OF DOSAGE—INTENSIVE ROENTGEN RADIATION—THEORY OF THE MODE OF ACTION OF RADIUM—LEUCEMIA AN OCCUPATIONAL DISEASE OF RADIOLOGISTS—RADIUM IN ADENOPATHIES AND DISORDERS OF INTERNAL SECRETIONS.

BERLIN, December 15, 1913.

THE treatment of cancer by means of radioactive substances is a subject that interests not only the medical profession and the sufferers from cancer, but also the public in general. Throughout Germany funds are being raised to provide the hospitals with supplies of radium and mesothorium. The greatest obstacle is encountered in the high price of the radium salts. But recent investigations have shown that by means of certain forms of apparatus it is possible to utilize the Roentgen rays in such manner as not merely to take the place of but actually in certain respects to surpass radium and mesothorium. The Berlin Medical Society devoted its meetings of December 3 and 10 to a full discussion of the above subjects.

At the former meeting Bumm reported his experiences in the treatment of 108 cases of cancer of the genital organs in women. Apparently in every instance the use of radium produced good results. A swelling of the growths was noticed shortly after the use of the radium emanations; later the tumors underwent a process of shrinking. Ulcerations healed over. In contrast to these fa-

vorable effects there may be pronounced injurious effects. If there are employed large doses of radium for the purpose of obtaining a deep and extensive action, there results a fibrous induration of the tissues which is followed by their hyaline degeneration. Perforations and stricture formation are further consequences. These effects may be manifested from one-half to one year after the application of radium. The most injurious in this respect are the secondary radiations. The statement that radium rays have a selective action upon carcinoma cells is applicable only in the case of moderate doses of the rays.

The most important question with reference to the radium treatment of cancer is the following: Is freedom from recurrence to be expected after this treatment? The short time that has elapsed since the introduction of this method of treatment has not provided any statistical data upon which one might base an answer to this question. But the microscopical examination of organs that have been subjected to the action of radium has thrown light upon this problem. It was demonstrated in one case that at a distance of 9½ centimeters from a healed carcinoma of the cervix there was a carcinomatous gland. In another case, at the site of a former cancer there was a fistula with cancerous metastases. In general it may be said that glands within 5 centimeters of the focus subjected to the radium emanations are favorably influenced. At any rate, the microscopic examination of the metastases has not demonstrated any pronounced malignancy of their cells, as is illustrated in the following case: After the application of the radium rays to a carcinomatous uterus, this organ was removed; while at the same time cancerous tissues in the broad ligament were left behind. In spite of this, the patient was apparently well one year after the operation. Of the 108 cases reported by Bumm, there have been 15 relapses. The general rule has been established that the younger the patient the worse is the result to be expected from the effects of the radium therapy in cancer.

As regards dosage, Bumm states that 50 to 100 milligrams of mesothorium are sufficient. The use of 200 to 300 milligrams is a grave error, for the larger doses frequently give rise to fever and other disturbances. Small doses at greater intervals and applied for a longer duration of time produce the best results. As a filter, aluminum or brass, but not lead, should be used. In addition a covering of rubber is recommended. The radium or mesothorium should not be brought any nearer than 3 to 4 centimeters to the tissue to be acted upon.

Recently certain *x*-ray tubes have been constructed that permit the use of intensive Roentgen radiations. With the use of these tubes it has been found possible to influence favorably a cervical carcinoma through the abdominal wall. Since the *x*-rays traverse the healthy soft parts before they reach the focus of disease, this method of treatment is particularly of value as a means of influencing the glands and metastases. Whether a combination of *x*-rays and radium is more efficacious than either of these alone remains for the future to decide. At any rate, up to the present time the best results have been obtained with the *x*-rays. It is as yet impossible to state whether radiotherapy is a reliable agent in the treatment of malignant growths. Nevertheless, there is ample evidence that certain inoperable cases have apparently been cured by this method.

"The Status and the New Aims of Radium and Mesothorium Therapy" was the subject of a paper by Paul Lazarus. He explains the action of the rays as follows: The cell nuclei provide centers of attraction for the secondary radiations, in which centers the phosphorized proteins play the chief rôle. In addition ferments are active, the radium acting as a catalyzing agent, with the result that a toxic nuclear and consequently a cellular destruction is brought about. The radium rays have no elective affinity for the cancerous tissues. But the latter are in a more susceptible condition than the former. Of great importance is the proper dosage. If this is too scant the tumors grow rapidly. The use of 150 milligrams of radium at the initial treatment is to be regarded as sufficiently potent. The injurious effects on the skin are less than in the case of *x*-ray treatment. The mucous membranes are attacked only by the larger doses. By means of the colloidal metals a secondary radiation may be evoked. Deepseated tumors should be brought to the surface by means of a surgical operation. Up to the present time the best results have been obtained by means of surgery, followed by the preventive application of radium. Cutaneous and inoperable carcinomata should be treated from the outset with radium, high fever and cachexia being contraindications. Injurious effects may occur years later. Leucemia may be regarded as an occupational disease of radiologists, seven cases having already been reported. Radium treatment has produced temporary improvement in the adenopathies and in cases of anomalies of the internal secretions. Radium has also been tried in pulmonary tuberculosis, on the basis of the bactericidal and hyperemia-producing properties of the radiations.

Only a few points may here be noted from a review of the extensive discussion that followed the reading of the above papers. Von Seuffert, of Munich, reported that he had treated 152 cases of cancer with small doses of thorium. Three-quarters of the cases were treated without the Roentgen rays. There were 103 inoperable cases. In all instances the effect of the treatment was a favorable one, as evidenced by the cessation of bleeding and pain. In 31 cases a clinical cure may be said to have taken place. The *x*-ray treatment is more available for both physician and patient. Joseph Hirsch has treated 126 cases of cancer with good results. In some of these complete cures were apparently obtained. The best results are obtained in sarcoma. Bickel has observed among a series of very bad cases seven fatal terminations, but otherwise without exception favorable results. H. E. Schmidt discussed the late injurious effects. In particular he believes that the intensive Roentgen apparatus will produce ultimate injurious effects. Alfred Alexander believes that by the observance of proper intermissions in the treatment the injurious effects are almost entirely avoided. He also advocates the use of small doses. At the same time the general condition of the patient should be looked after. The tonic effects of arsenic and other remedies are helpful adjuncts in the radiation treatment of cancer.

8. Psychanalysis. S. A. Tannenbaum.
9. Cutaneous Epitheliomata Cured by Sunlight. H. H. Seelye.

1. Tumors of the Carotid Body.—J. C. DaCosta states that one is justified to-day in concluding: First, that the carotid body exists more frequently than was formerly believed; that it is of unknown function; that it should undergo fibrous atrophy at or soon after puberty, and that if such atrophy fails to occur the carotid body will probably enlarge and such enlargement is to be regarded as a tumor. Second, tumors of the carotid body are of the type of endotheliomata known as peritheliomata. Third, these tumors, originally innocent, usually pursue a long course. Rapid growth is exceptional until years have passed. Sooner or later they tend to take on rapid growth and to cause functional involvement. Rapid growth signifies malignancy. A malignant change is sarcomatous in character. Fourth, the growth is almost invariably unilateral. Fifth, the carotid body is associated intimately with important vessels and nerves, its position being retrocarotid rather than intercarotid. It has a large blood supply which is carried by the ligament of Mayer. Any injury to the carotid body produces profuse hemorrhage and if an operation is once started it must be completed or the man will probably bleed to death. The relations of the carotid body render any operation difficult and dangerous and make postoperative complications probable. Sixth, the carotid body is intimately associated with nerves, involvement of which will produce symptoms. Tumors are lifted by the pulsating carotid artery, and are movable laterally, but not up and down. Seventh, operative interference is comparatively safe when the tumor is recent and small, but is fraught with grave peril when the tumor is old and with especial danger if it is large. The larger and older the tumor the more probable it is that ligation of the common carotid or of all the carotids will be necessary in the removal and that injury to important nerve structures will be almost inevitable. Early operation may enable one to dissect the tumor from the carotids, or to get off with tying the external carotid alone. As these growths tend strongly to become malignant eventually, as early operation is reasonably easy and comparatively safe, as late operation is difficult and highly dangerous, and as sooner or later the tumor, if let alone, will kill the patient, early operation is imperative.

4. Etiology of Beriberi.—W. P. Chamberlain states that highly milled rice lacks some substance necessary for proper nerve nutrition, and that this substance is contained in the polishings obtained during the process of milling. The neuritis-preventing substance is in the outer coatings of the rice kernel. Only a very small amount of the neuritis-preventing principle is necessary to maintain health. The same substance resides in many common articles of diet such as egg yolk, barley, peas, and beans. It is also present in yeast. This element is destroyed by a temperature of 120° C., and also by prolonged boiling. A safe undermilled rice may be rendered beriberi-producing if cooked by steam under pressure. There is considerable reason to believe that the neuritis-preventing principle is an organic base. Funk calls the substance he isolated a "vitamine" and has shown that it consists of three fractions. Not all authorities accept the polished rice theory of beriberi production. In some instances, particularly in certain asylums, on ships, and in South America a disease called beriberi is reported to occur among persons who eat little or no rice. Three explanations of these are offered: First, the diet may be an unbalanced one, lacking the neuritis-preventing substance, even though it is not a rice diet. Secondly, the neuritis-preventing principle originally present in the food may have been destroyed by excessive heat, for instance by cooking with steam under pressure. This possibility appears to have received no investigation. Thirdly, the term "beriberi" may include several varieties of peripheral neuritis caused by lead, arsenic, and alcohol, and by bacteria. That a diet of rice deprived of its pericarp will produce one type of neuritis in man, as well as in fowls, seems fully established. But it by no means follows that there may not be still other types of endemic tropical neuritis, each presenting a symptom complex not readily to be distinguished from that of Oriental beriberi, and each having a distinct etiological factor which still awaits discovery.

5. Auricular Fibrillation in a Child.—By S. G. Ehrenreich. (See Medical Record, January 10, 1914, page 83.)

6. Streptococci in Relation to Endocarditis and Rheumatism.—By E. C. Rosenow. (See Medical Record, December 20, 1913, page 1148.)

7. Herpes Zoster Oticus.—V. Dabney states that according to Chavanne primary herpes zoster of the ear is exceedingly rare. The latter observer reports a case of his own, in which he attributes the deafness and tinnitus to labyrinthine invasion by the specific herpetic poison. Hunt believes that those cases in which there is a long interval between the auditory disturbance and the eruption or other manifestation of the disease, are properly classed as herpes zoster oticus, and that the hypacusis is most likely due to involvement of the eighth nerve somewhere in its course, perhaps most often in its internal ear distribution. The author reports a case which could not strictly be classed as primary, but clinically it was such, as there was no manifestation of herpes at the time, nor had there been any manifestation for nearly two months. The points of interest in the reported cases are chiefly as follows: (1) Long period (month) between deafness and any definite herpetic manifestation. The pain could not be classed as such, as it was merely an unexplained otalgia. (2) The severity and persistence of the postherpetic otalgia—four months after healing of the last vesicle. (3) Futility of any treatment directed to a cure. (4) Success of high frequency electricity in temporary alleviation of pain. (5) Marked neurosis, which at one time exaggerated the symptoms, and yet at another allowed the substitution of sterile water for codeine, producing relief from pain, as much from one as from the other. (6) Successive crops of vesicles, or more properly, successive vesicles, as they appeared singly, and not in crops as is usual in other cases.

**1. The Air as a Vehicle of Infection.**—C. V. Chapin presents a general review of the facts regarding infection through the atmosphere. This includes the subject of dust and droplet infection, the importance of which in the author's opinion has been overestimated. The question of dosage in causing disease is all-important, but qualitative studies have been somewhat neglected. The precipitation of germs in indoor dust, which has been allowed to accumulate, is no indication of the number in the atmosphere at any one time. There is but little evidence of aerial conveyance except in a few conditions, like bubonic plague. There is still some difference of opinion among physicians in regard to chickenpox, measles, rubella, etc., but the evidence is not conclusive. Anthrax ought to be more easily airborne than other diseases, and inhalation of dust in the atmosphere may be the cause in some cases. The decrease of the pneumonic or internal type, however, in those exposed has been much greater than that of the external or contact type which would indicate the value of precautions taken in recent years against the inhalations of dust. The author concludes that aerial transmission of disease is rarely an important factor except possibly in tuberculosis, but the last word has not been said in regard to this disorder.

**2. Gastric Hyperacidity.**—A. Schmidt states that in the treatment of this condition the principal point is not to confine oneself entirely to the stomach, but also to calm and strengthen the nervous system. Some patients are best treated by being sent at once to a hospital or sanatorium, and this should be demanded in every severe case. Naturally, one should try first to reduce the secretion. Atropine accomplishes this result, but its continuous use is not advisable, nor is that of the alkalies, which may irritate the gastric glands. The author favors the use of magnesium oxide combined with a small amount of belladonna and a purgative, such as sodium sulphate. Silver nitrate owes its excellent influence on hyperacidity to its astringent effect on the circulatory cells and partly to its blunting the hyperirritability of the mucosa. For the latter purpose it should be given half an hour before meals; for the former, a solution to rinse the stomach should be used in the morning with the aid of the tube. Diet is perhaps more important, and foods that act as secretory stimulants, like spices, coffee, strong alcoholics, etc., should be avoided. As to special diets, it is difficult to keep them up for any length of time, and the author has long returned to a mixed diet and strict observance of the following rules: All food must be thoroughly cooked and carefully minced. The stomach must come to rest at least once during the twenty-four hours and the times of the meals should be changed to secure this. Drinking should be generally diminished and restricted to times when the stomach is not filled with food, especially in cases of ptosis. If the condition is severe or combined with ptosis the patient should stay in bed for two weeks. Sometimes hot compresses are used to bring relief—twice daily for two hours. At night they are replaced by cold hydropathic compresses. Washing the stomach is indicated only when the hyperacidity is based on catarrh.

**7. Radiography of Gastrointestinal Tract in Functional Nervous Disorders.**—By Pierce Clark and A. H. Busby. (See MEDICAL RECORD, July 19, 1913, page 135.)

**10. Heredity in Bone Lesions.**—J. Ransohoff reports the histories of four patients suffering from bone lesions in three generations of one family. The grandmother died of pulmonary metastases of sarcoma of the femur following spontaneous fracture. One son died from recurrent hemorrhages following an osteosarcoma of the femoral neck. Another son with osteitis deformans involving the bones of the lower limbs and progressing into the spine died from nephritis. A daughter of the last patient showed on examination at the age of six months a fracture at the lower end of the left tibia. Various operations were performed, leaving marked shortening of the left leg. All these operations during childhood failed to better matters. Trophic changes, ulcerations, etc., made life so intolerable that amputation was resorted to when the child was sixteen years old. In all these cases bone tissue was probably by heredity a *locus minoris resistentiæ*.

**11. A Case of Brain Abscess.**—C. E. Reynolds reports a case of brain abscess with obscure symptoms due to Pfeiffer's bacillus and a staphylococcus, and involving the white matter of the angular and interparietal lobes and the left optic thalamus. The early symptoms, besides headache and vomiting, to which the patient was subject, were verbal amnesia and inability to use the right word. Later the symptoms became more severe and included a slight paralysis of the right upper limb and beginning optic neuritis of the nasal side of each disk appeared. Operation was performed and two small abscesses were drained. Death occurred from the formation of a third abscess cavity on the thirteenth day after the operation. The case indicates the importance of early exploratory operation in doubtful cases of intracranial disease before optic neuritis has developed.

**1. Linitis Plastica, or Leather-Bottle Stomach.**—Sir John Bland-Sutton states that this condition was first described as a distinct disease in 1854 by William Brinton, although it had been recognized at least two centuries before. The leather-bottle stomach is greatly contracted in size and its capacity is markedly diminished. Instead of being 12 inches long and 5 inches

wide, as the normal organ, it may be 4 inches long and 2 inches wide. Instead of being flexible its walls are rigid, thick, and hard like a leather pouch. When pressed upon the wall does not collapse, and, as Brinton pointed out, it resists even considerable pressure, and returns to its original shape like a large artery or a caoutchouc bottle. The thickening involves the gastric walls from the cardiac opening to the pylorus. At the pyloric end it is sharply defined, and the thin walls of the duodenum are in striking contrast to the thickness of the walls of the stomach. The condition predisposing to linitis plastica is an ulcer in the mucous membrane, which permits the connective tissue planes of the stomach to be permeated by infective agents associated with the ulcer, and the new connective tissue grows in response to the irritation they cause. The sharp limitation of the thickening at the pyloric ring accords with the anatomy of the stomach. The leather-bottle stomach produced by malignant disease has a similar history. A cancerous focus in the gastric mucous membrane—probably a chronic gastric ulcer which has become malignant—allows epithelial elements to permeate the connective tissue planes of the stomach.

2. **Operating to the Clock.**—J. O'Conor for years past has acted according to the idea that the success of a serious surgical operation on the unknown quantity, the human body, is in direct ratio to its rapidity. He emphasizes the fact that quick operating is not of value *per se* unless combined with conscientious and thorough workmanship, and unless compatible with the removal of the *fons et origo mali*, whether this be an infected appendix, Fallopian tube, or gall bladder, or other cause. The system employed by the author in timing operations is as follows: The nurse in charge of the operating room writes down the time by the clock the moment knife enters skin, and when final skin suture is tied calls out the time occupied. This is immediately written down by her on the operation slate, under the supervision of the resident medical officer, who later on in the day fills in all details in the operation register. The author has found that the employment of ether by the open method has materially diminished the percentage of cases of shock. In serious cases of anteoperative toxemia he has found the placing of the patients permanently out of doors, immediately after operation, to be of immense service, and during the early convalescent stage in such cases he has also found that there is no drug, or anything else, equal to the daily administration of a pint of the best dry champagne for a week.

4. **Eosinophile Ascites.**—H. D. Rolleston reports the case of a male aged 22 years who at the end of September, 1913, had colic and vomiting two days after eating some fish, followed gradually by jaundice and putty-like stools, and about the middle of October by transient pruritus. He was admitted to St. George's Hospital on November 4 with considerable jaundice, some rather vague resistance in the right loin, an enlarged and tender liver, and tenderness near the umbilicus. The gall-bladder and the spleen could not be felt. For a time there was some apparent improvement, but on November 21 ascites was obvious, and on December 3 seven pints of fluid were removed; this contained red blood corpuscles, lymphocytes 46 per cent., endothelial cells 29 per cent., eosinophiles 22 per cent., polymorphonuclears 2 per cent., and mast cells 1 per cent. The Wassermann reaction in the ascitic fluid and in the blood was negative. Examination of the stools did not reveal the presence of any ova of worms. The urine constantly contained bile pigment, but not bile salts, and there was no sugar; in the last week of life there was a trace of albumin on two occasions. Early in December the base of the right lung was found to be dull on percussion, breath sounds to be absent, and skiagraphy showed opacity. On December 12 the patient had severe abdominal pain, and the pulse rose to over 100. The pain gradually increased and necessitated the use of morphine. On December 14 the patient became comatose and died on the following day. His temperature, which had always been about normal, rose to 99.6° F. on December 14. The necropsy showed the following: The skin was universally jaundiced. There was acute peritonitis with a copious effusion which contained polymorphonuclear cells 79 per cent., lymphocytes and endothelial cells 21 per cent.; a count of 400 white cells showing two eosinophiles. There were numerous minute secondary growths on the peritoneum, especially on the diaphragm, which was much thickened. There was a primary "colloid" carcinoma in the ascending colon just above the ileocecal valve, which was not narrowed. The cecum was high up in the abdomen on the right side.

5. **Syphilitic Paralysis of the Esophagus.**—R. Saundby reports the case of a man, aged 35, who consulted the author on March 30, 1895, complaining of his sight going dark at times, with giddiness, but no pain; he was occasionally faint; he had been ill for a month, and was gradually getting worse; he did not think he ever lost consciousness, and he had never fallen down. His previous health had been good, and he had never had gout or rheumatism; twelve years before he had had a primary syphilitic sore. His father was alive and well; his mother was alive but insane. Two brothers were alive, one well; the other suffered from chronic heart disease, and a sister, aged 42, also suffered from chronic heart disease and kidney mischief. There was no other case of insanity in the family known to the patient and no case of fits. During the attacks, which began in the fingers of the right hand and ran up to the shoulder, the arm seemed powerless; his head was drawn to the right, and his speech became thick and he saw double. Ophthalmoscopic examination showed some haziness of the margin of both discs, especially the left. Physical signs were normal; the urine was thick with urates, but free from albumin and sugar. The patient was not seen again until November, 1902. He had had difficulty in swallowing, but there was no obstruction to the passage of a sound into the stomach; fluids regurgitated when he attempted to swallow them, and for eight days it was necessary to feed him with a tube. Under anti-syphilitic treatment he made a rapid recovery and swallowed naturally, although he could not drink a draught of liquid. There was no giddiness, but he had a sensation of warmth down the left side and the left hand was unable to distinguish between hot and cold. There was no analgesia or anesthesia. The knee-jerks were present; the pupils reacted to light, and there was no Romberg's sign. On March 11, 1904, he thought that his swallowing was not quite what it had been, but there was no apparent difficulty either with solids or liquids. There was still imperfect sensation of heat in the left hand; his eyesight was good. Paralysis of the esophagus is generally dealt with in a summary fashion by systematic writers. The causes given are diphtheria, hemorrhage, softening, tumor, or sclerosis in the brain, and pressure from enlarged lymphatic glands on the vagus nerve or disease of the vertebræ, chronic alcoholism, or lead poisoning setting up a neuritis.

### Berliner klinische Wochenschrift.

*January 9 and 26, 1914.*

**Sport and Accidents.**—Bartsch makes of this subject what he terms a "hygienic-surgical study." Athletic

heart is first mentioned, and this is so common in sport of all kinds that we now hear of a "ski heart." There are, however, numerous accidents in the narrower sense of the term, including some very simple ones, beginning with excoriations and sprains and ascending gradually until fatal injuries and sudden death are reached. Naturally the better the constitution and condition of the athlete, and the less the hazard involved, the less we expect to see of sport-injuries. The author thinks it might be possible to devise a "scale of risk" applicable to all sports. This would begin with individual sports, after which a composite could be reached. Naturally the subjects of contributory neglect and prophylaxis could then be formulated.

**Magnesium Treatment of Tetanus.**—Stadler concludes his article as follows: he and others tested Meltzer's method in the Balkan war. There were no recoveries reported, but death resulted in three of five cases from cardiac failure and not from tetanus. Such figures show no comparison with the results of Baccelli's method in the hands of Italians. For some unknown reason the German surgeons do not get such favorable results. The claim that in Italy the disease runs a mild course is entirely unfounded. Again, English, French, and Russian surgeons have obtained excellent results from Baccelli's method, equal to those of the Italians. The author has made experiments with phenol and magnesium sulphate conjointly upon animals and will report upon them soon. The serum treatment caused an initial great reduction of mortality, while symptomatic treatment with phenol and magnesium has added to the percentage of cures, either alone or with serum. For the present we cannot decide upon the relative advantages of the two chemicals. In general phenol seems to excel magnesium by a wide margin, but if the latter is given subcutaneously instead of intraspinally the margin is somewhat reduced. During the next decade we should determine which of the three known antidiphtheritics is really superior.

**Sarcoma as a Result of the Uviol Lamp Treatment.**—Simon first applied these rays for cosmetic purpose to a small growth over a woman's clavicle. Originally a wen, it was excised. Inflammation set in, leaving a blue-red scar, which remained unchanged for years. In the meantime psoriasis developed and was treated with the uviol lamp. The small, slightly keloidal scar from the operation was incidentally treated with the rays. The scar proliferated until a large sarcomatous tumor developed and was excised. This condition represented an ordinary sarcomatous degeneration of scar tissue. The author discusses the pathology of this apparent transition, but is silent on the pathologic activities of the rays.

**Cure of Peritoneal Tuberculosis by Direct Insufflation of Nitrogen.**—Brückner after two laparotomies and the use of all manner of physical resources, tapped the abdomen and gave exit to 2½ liters of ascitic fluid, infused 500 c.cm. of nitrogen, which was well borne but caused no diminution in the amount of ascites. In nine days after he infused 600 c.cm. without attempting to withdraw any fluid. On a third occasion 800 c.cm. were used with no attempt to draw off fluid. Within a month later all ascites had disappeared. The general improvement has been marked. No return of ascites.

**So-Called Relapsing Umbilical Colic in Children.**—Küttner quotes a recent statement by Moro to the effect that in appendicitis in children we often find what he terms a "relapsing umbilical colic." Küttner emphasizes that a consequential relationship has not yet been proven here, although the colic is said to disappear after appendectomy. The author has had several personal cases, of which one is as follows: a boy aged 9, healthy and vigorous, began to suffer from crises of colic which was most intense at the navel. The attacks succeeded each other with repeated frequency. The duration was at times brief, and attacks sometimes were precipitated by rough play or prolonged walking. Pain often occurred while dressing in the morning, so that the boy fainted. Tenderness over McBurney's point not invariably present. In fact, there was no tender spot anywhere over the abdomen. Appendectomy revealed that the appendix was healthy enough, but very long, rotated, and kinked. The pains at once ceased. The entire series of cases were close to this type. Appendicitis seems to have been absent, save perhaps for brief adhesions which may not have been of inflammatory origin. Fecal calculi were found several times. A case of clinical appendicitis was included, but on operation a mere rudimentary origin was found, obliterated. It was probably responsible for the pains which went away after appendectomy.

**Staphylococcus Sepsis After Furunculosis.**—Cassel reports a case of this sequence, which he sums up as follows: the disease was a metastatic pyemia following superficial suppuration on the surface—from small furuncles. Before the general infection there were an abscess in the axilla and rheumatoid symptoms in the lumbar region. The possibility of a renal lesion was naturally thought of, and this was later verified by a diagnosis of metastatic inflammation of the right kidney. A collection of pus became encysted in the latissimus dorsi; and after this was opened and drained the patient seemed to have recovered. One month later, however, it suddenly became evident that a second metastasis had taken place. The urine for the first time revealed that the parenchyma of the kidney had become involved. There was phlegmonous perinephritis, the entire renal fat being involved, while the kidney was cyanotic and the seat of an abscess. Despite the number and severity of the lesions, nephrectomy seemed contraindicated. Other metastases began to appear, indicating a general pyemia. The treatment was, therefore, generalized and an autovaccine (staphylococcus) was used. The escape of pus from the original exploratory incision, as well as by the urine, served to limit the process, and it could be seen that much of the renal parenchyma was still intact. Patient made a complete recovery. His liver metastasis was of such character that it could readily be opened and drained.

### Münchener medizinische Wochenschrift.

*January* 13, 1914.

**The Disease of the Chamorros.**—Leber, an ophthalmologist, in association with Prowazek, the naturalist, describes an affection which is common among the inhabitants of a small island in the Guam group, now owned by Germany. It has been called the "cold woods-disease of the Chamorros," and bears some relationship to the "amok" disease, sometimes regarded as psychic epilepsy. The islands have been visited by many plagues and endemic diseases, so that the healthy are in a minority. Psychoses *per se* are, however, not much in evidence; hence the striking peculiarities of the disease in question. The author describes a case as follows: Strong, undersized Chamorro man, known to suffer from ascarides and ankylostomiasis. Has never abused palm wine, nor have his ascendants. The patient is an only child. Father healthy, but mother suffers from fits of some sort, in which she speaks confusedly, laughs, etc., but does not lose consciousness. Attacks occur once weekly and last half a day. They begin as a rule with headache or gastralgia. Aside from these seizures the mother is healthy. The patient

is usually sad in behavior, and often has the obsession that something bad has been "wished on him." When this feeling grows strong enough he hides himself, and may suddenly leave his comrades. He has ideas of grandeur and superiority at that time, and looks down upon the other Chamorros; and even looks down upon his own family. Since at this period he tends to wander into the woods (bush) his illness is termed "waldkrankheit." From these attacks he recovers suddenly, just as the seizure begin suddenly by a collapse and loss of consciousness. Seizures of this sort began at the age of sixteen and between the ages of sixteen and twenty-four he has had five of these attacks. The phenomena during these seizures point to a complete forfeiture of all ordinary ethical sense. On one occasion the patient showed violence and sought to attack his family with a club; it was necessary to restrain him forcefully. As a rule there was no confusion of sex. He had homosexual dreams and longings as well as heterosexual. As a boy he had had coitus in the posture of beasts with other boys, had practised mutual onanism, etc. He was in these seizures unable to find a partner; but justified abnormal coitus because it is practiced by animals. A question of great importance is the association of these spells with the "amok," which has been so extensively studied from the viewpoint of epilepsy. In the latter the freedom of will is forfeited, deeds of violence are unimpeded, and the subject is wholly irresponsible. The "amok" is not really limited to certain countries, save by name, but something akin has been seen throughout the savage world. The element of suggestion plays a considerable rôle in some cases, and a genuine murder lust may supplant all other phenomena. In regard to the Chamorro disease alone, the author finds no evidence of suggestibility, and which may be set down as epileptic in character when psychical phenomena recur periodically, even although suggestive influences are not wholly wanting. Its relationship with other kinds of "amok" is still problematic.

**Clinical Studies of the Dialysis Procedure (Abderhalden).**—Oeller and Stephan conclude their serial article as follows: to prove the organ specificity of a ferment, the field of investigation must be widened, so that for "specificity control" several non-specific organic substrata may be utilized. For organ control the entire research must be conducted with both active and inactive serum. A doubtful serum cannot be investigated; one desires a serum which gives either positive or negative results. The author's final conclusion is that his studies as to dialysis can only be conducted in special laboratories; we see in these the sole way to make a biologic reaction serviceable in the clinic.

## Deutsche medizinische Wochenschrift.

*January* 15, 1914.

**New Methods of Treating Deafness and Subjective Sounds.**—Hegener sums these up in somewhat meagre terms, despite the extent of his paper. He believes that the old, acoustic methods have not at all been supplanted by the new costly apparatus. Nothing new in principle has been introduced, while the "new" results are lacking in comparison with the old. Diathermy and radium are so dangerous as to be safely applicable only by experts. Naturally there is no denial that they may eventually come into general use, through prolonged study of techniques. The daily press is largely responsible for the vogue of new measures, and should in some way be antagonized. The patient, thus deceived, blames only his doctor and the profession.

**Inversion and Total Prolapse of the Puerperal Uterus.**—Allmann emphasizes the great rarity of inversion in the puerperal uterus. Naturally in the latter inversion and prolapse cannot always be dissociated, but the author's title seems to imply a special degree of prolapse. With incomplete inversion there is no prolapse, while total inversion may or may not mean total prolapse. The author's article is devoted entirely to the inversion feature, representing one more addition to the sparse collection of cases. Concluding, he says that total inversion is a severe condition, irrespective of prolapse. In the hopeless cases we must wait, while if the prognosis is not hopeless we may attempt a gentle reposition. Should this fail, bloody reposition becomes necessary. When there is no clear indication the uterus must be extirpated.

**Bone Necrosis and Sequester Formation.**—Axhausen seeks to account for this sequence. We know he says that in small necroses, despite infection, there need be neither demarcation nor sequestration. In a rib stump in an empyema operation, the traumatic marginal necroses despite infection does not necessarily mean demarcation. The process is the same as that seen on the cranium, where a granulating wound is seen on a skull deprived of periosteum. The old surgeons explained this phenomenon by the term "insensible exfoliation." As a matter of fact there is here no exfoliation; only an internal metamorphosis of a superficial necrosis. The same thing occurs in the mild pneumococcus osteomyelitis of children. Here we see despite laying bare of bone and suppuration no sequester formation may occur. As bone after infectious inflammation starts in to repair, the surrounding tissues which possess the power of ossification force themselves into the necrotic area and bring about an internal restitution of bone tissue. If this area is small no sequestration results. Only when it reaches a certain size does sequestration occur. Determining factors are an increased degree of damage to the bone, and a high degree of infection.

**The Hypophysis and Diabetes Insipidus.**—Römer sums up his long study of this relationship as follows: Polyuria is often seen after fractures of the skull, contusions, etc.; representing acute injuries; as well as in connection with tumors, hydrocephalus, etc., representing chronic stasis. Hence the hypophysis is not the sole occasion for polyuria related to cranial stasis. In inherited polyuria anomalous hypophyseal development has been accused. In addition to these conclusions, there are others which refer directly to an original relation of diabetes insipidus; to the hypophysis cerebri. This does not necessarily mean an overaction of the pars intermedia, but rather to a withdrawal symptoms in the gland, especially the intermedia, indicating a failure to form a certain substance.

**The Treatment of Cerebral Tumors in the Child.**—M. L. D'Astros points out that the essential conditions underlying the radical or surgical treatment of brain tumors in childhood, is the exact localization of the tumor and its accessibility. Hydatid cysts and gliomata, if within reach, are amenable to surgical intervention. This can not be said of the tuberculomata which constitute the majority of the cerebral tumors of childhood. The reason is that these tumors are usually multiple and are accompanied by other manifestations of tuberculosis. Marked meningeal reactions and meningitis contraindicate the radical treatment.—*Annales de Médieine et Chirurgie Infantiles.*

**The Myotonic Reaction.**—M. I. Babonneix describes this reaction as consisting essentially in an increase of the muscular excitability both to electrical and to mechanical stimuli. The excitability of the nerve trunks is not increased. Appropriate galvanic stimuli produce a slow and prolonged muscular contraction. This reaction is present in two conditions: in Thomsen's disease and in the myopathies. In the former it occurs early and is constant. In the latter it occurs early but is not constant.—*Gazette des Hôpitaux.*

## Insurance Medicine.

**Progress of Life Assurance in the Past Thirty Years.**—In the presidential address delivered to the British Life Assurance Medical Officers' Association on January 7, 1914, by Dr. R. Kingston Fox, the progress of life insurance medicine in the past thirty years was traced. In referring to the greater fullness of reports of life insurance examinations the speaker calls attention to some schedules, especially those of well-known American offices, which demand from the examiners answers to a series of questions of extraordinary length and multiplicity and remarks that surely if the medical mind is fatigued by the detail labor thus required, it will be less ready to give, what is really wanted most of all, a reasoned and balanced opinion, under a due sense of responsibility, of the healthiness of the life in question.

As to family history the opinion is advanced that upon the whole rather less importance has come to be attached to the facts of family history in estimating lives. This seems to be due to the fuller recognition of the causes of disease, or rather perhaps of their immediate or exciting causes. Since 1884 the connection of many diseases with the life history of microorganisms has been established and the onset of such diseases is seen to depend upon external causes to an extent not previously supposed. Hence the factor of inheritance looms less large in the field of prognosis. Probably, however, it will still be well to give it an important place. So far as personal history is concerned fresh light has been thrown upon many questions.

Pleurisy with effusion has been shown to be most often tuberculous and as such should be regarded as an adverse factor needing consideration. As yet it is too soon to say whether recent improvements in the treatment of syphilis, and especially the use of salvarsan, will lessen the adverse influence of a syphilitic history. For it is the remoter consequences of this disease and especially general paralysis of the insane which we have to take into account in our prognosis, and a good many years' experience of the newer remedies will be required before it can be determined whether they prevent the onset of these more remote phenomena.

Surgery has rendered feasible various abdominal operations and other formerly difficult operations and has thus tended to render less serious from the life insurance aspect many disorders for which these operations are performed. As to the condition of the heart Dr. James Mackenzie has done much to alter the change of outlook on heart disease. There is no doubt that not a few lives having a fair prospect of longevity used to be rejected for insurance on account of valvular defects which were well compensated, and that we are now able to recommend many such cases at an extra rating. The measurement of arterial tension has not as yet taken a recognized place in insurance medical examination. In this matter our American colleagues have been before us and have done good work on the detail of the methods in use and on its bearing upon the prospects of life. There is a disposition among the American offices to require a record of the systolic blood pressure whenever the age of the proposer is forty-five years or more, and to fix a limit of about 150 mm. at and over which no life is accepted on normal terms. Upon the whole, Fox suggests that the time has come when the English medical forms should include a question on the arterial blood pressure which is to be reported on whenever there is any history or suspicion of heart or kidney disorder and in all cases without exception in which the age is forty-five or over.

The evidence which has been accumulated during the past generation with regard to functional albuminuria justifies a clear conviction of the reality of this disorder, and the time seems ripe for the definition of its true nature and its relation to the bodily processes. It is suggested that taking into consideration the lesser risks of life in the tropics owing to the prevention of malaria and other diseases of the tropics, to improved manner of living, improved sanitation, and also when the fact is regarded that most of those who go to the tropics are picked lives and that provision for holiday and furlough has now become systematized, may not the time have been reached when those who go out under ordinary circumstances to India and perhaps also to China, may be taken without extra rating?

The speaker in referring to lymphorheumatic diseases, said that it may be permissible to point out that the recognition from family records and personal history that a proposer is liable to this group of disorders, would afford a fact of value in estimating his prospects of life. It may be added that it often supplies a determining factor in judging of the necessity of antityphoid inoculation under particular circumstances. Stress is laid on the fact that tuberculosis and cancer account for about 15 per cent. of the deaths of insured persons, while a more important fact is that many of these deaths occur in early adult or middle life. As to tuberculosis we know that a great change has occurred; that the discovery of its living germ has given an immense impetus to the movement for treating the disease on hygienic lines. And the results are seen in the returns of deaths, for the mortality from phthisis has not only declined rapidly but at an accelerated rate. For adults in England and Wales of over twenty-five years of age the death rate is now about 40 per cent. lower than it was thirty years ago, and the fall has been greater in the case of women than of men. If the present rate of decline continues for another thirty years, and there is good prospect that it will do so, the old plague of consumption will wear a very different aspect in all civilized countries. This is a remarkable prospect. For insurance purposes it must be discounted a little, because the returns are for the whole community, and the insured classes have already been in the enjoyment of some of the advantages which are now extended to those who are poorer; it follows that they may not share to the full extent in the reduction of mortality. Yet evidence enough is left to greatly modify our outlook. In view, then, of the present lightening of the risk of phthisis and the prospect of its further reduction, we are surely justified in treating those proposers who show a liability to tuberculosis with less rigor than in the past. We may now, in his opinion, regard a family history of tuberculosis as of little importance if the subject himself has sound lungs and good habits; we may accept many cases at tabular rates where the suspicion of liability rests on slight evidence; and we may be content with lower ratings where these are called for.

# Book Reviews.

Diseases and Deformities of the Foot. By John Joseph Nutt, B.L., M.D., Surgeon-in-Chief, New York State Hospital for the Care of Crippled and Deformed Children; Surgeon, Sea Breeze Hospital, etc. Illustrated; price $2.75 net. New York: E. B. Treat & Company, 1913.

This book of 286 pages is designed, as the author states in his preface, "for the use of physicians who have not had the time or the opportunity for the thorough study of this often neglected subject," and should be of value to the busy practitioner in his work. It will help him in treating the minor ailments, and possibly the more severe ones. Like most volumes of the kind, however, in the attempt to be practical, it sacrifices scientific accuracy. One is surprised to see the terms "rheumatism" and "sciatica" employed in the rather vague manner in which the author uses them. The illustrations are somewhat crude, and their captions are not carefully thought out, *e. g.* Fig. 18. In the practical portions of the book the author is at his best. On theory he is not so good. He shows a familiarity with modern textbooks, but not the wide reading would expect from an authority. This leads him into didactic statements that cannot be substantiated, *e. g.* the pronouncement on the cause of bunion. His terminology at times is slovenly, *e. g.* "osseous flat foot," "acute feet." One cannot help thinking that the author would improve his book greatly by threshing out his ideas with his fellows. They seem somewhat "insular."

Dysenteries. Their Differentiation and Treatment. By Leonard Rogers, M.D., F.R.C.P., B.S., F.R.C.S., C.I.E., I.M.S., Physician to the Isolation Ward (Cholera and Dysentery) Medical College Hospital, and Professor of Pathology, Medical College, Calcutta. Price, $3.75. London: Henry Frowde; New York: Oxford University Press, 1913.

This interesting work on dysenteries includes chapters on epidemiology which describe and differentiate the two great classes of amebic and bacillary dysentery. During his investigations Professor Rogers discovered the rapid specific action of hypodermic injections of the soluble salts of emetine in amebic dysentery. This discovery increased, naturally, the importance of distinguishing this variety of the disease from that caused by bacilli. Two autopsies which proved that death was not due to relapses of amebic dysentery furnished the proof that emetine injections can bring about rapid and complete healing of both very acute and very chronic amebic lesions. Out of 30 patients treated with emetine injections 3 died, making a mortality of ten per cent. compared to 43 per cent. in the series treated with ipecacuanha. The entrance to the hospital of all three fatal cases was too late to give a fair chance of recovery. Professor Rogers concludes that in cases treated with emetine the diet difficulties are much lessened and some solid food can usually be given about the third or the fourth day after admission. There are also a chapter on sprue, diagrams of the seasonal incidence of Indian jail dysentery in relation to rainfall and mean monthly temperature, of the seasonal incidence of dysentery, diarrhea, and hepatitis in Calcutta, and of the distribution of dysentery lesion in the intestines.

Leitfaden der Hygiene für Studierende, Aertze, Architekten, Ingenieure und Verwaltungsbeamte. Von Dr. Aug. Gärtner, O.O., Professor der Hygiene und Direktor des Hygienischen Institutes der Universität Jena. Price M. 8.60. Berlin: S. Karger, 1914.

This is the sixth edition of Professor Gärtner's textbook on hygiene. The chapters have been thoroughly revised and many abolitions made. Among the latter we note in the chapter on the pathogenetic bacteria in dirt a paragraph on the extraordinary vitality of the anthrax spores from the feces and cadavers of animals dying from splenic fever. The German law requires the burial of such animals in a separate, hedged burying place. In the chapter on residences and the planning of towns, Professor Gärtner mentions the garden city movements and regrets that the waterworks and the streets cost so much as to render them impractical as yet for the factory workers. There are additional paragraphs on anaphylaxis and serum disease in the chapter on artificial immunity, and newly inserted subdivisions on whooping cough and black-water fever.

The Principles and Practice of Medical Hydrology. Being the Science of Treatment by Waters and Baths. By R. Fortescue Fox, M.D. (Lond.), F.R. Met. Soc., Late Hyde Lecturer on Hydrology, Royal Society of Medicine. Price, $2.00. London: University of London Press; New York: Oxford University Press, 1913.

This comprehensive treatise on hydrology has a number of valuable rules for the use of baths in health and interesting information as to the medicinal waters of Great Britain and as to the climatic element in hydrological treatment. There is an index of the spas in all countries. Dr. Fortescue Fox is a believer in an after-treatment of a week or two spent in some exhilarating climate among the hills or at the seaside, with pleasurable recreation but without over-excitement or fatigue.

Die Therapie an den Bonner Universitätskliniken. Herausgegeben Von Prof. Dr. Rudolf Finkelnburg in Bonn. Price, 9.60 Marks. Bonn: A. Marcus und E. Webers, 1914.

The contents of this compendium are as follows: Internal Diseases, by Geh. Rat Prof. Schultze, Prof. Finkelnburg, Prof. Paul Krause and Prof. Stursberg. Pediatrics, by Prof. Esser. Nervous and Mental Disorders, by Geh. Rat. Prof. Westphal, Prof. Hübner, and Prof. Finkelnburg. Surgery, by Geh. Rat Prof. Gerré, Prof. Machol, Dr. Bayer, Dr. Els, Dr. Fruend, Dr. Geinitz, Dr. Krabbel and Dr. Syring. Ophthalmology, by Geh. Rat Prof. Kuhnt. Ear, Nose and Throat, by Geh. Rat Prof. Walb. Gynecology, by Prof. Reifferscheid. Skin and Venereal Diseases, by Priv.-Doz. Frieboes. Special Methods, by Prof. Dr. Stursberg. Therapy of Intoxications, by Prof. Dr. Finkelnburg.

Particular stress is laid on the negative results of the Bonn clinical practice in order that practicians may avoid the use of numerous methods proven by years of experience of the clinic physicians to be worthless. Details of the special technique of the kinds of treatment and the inclusion of diet lists and formulæ give the book increased practical worth. Each division is compiled by the privat-dozents and the professors of the respective clinics.

Roentgentiefentherapie. Ihre Theoretischen Grundlage, ihre praktische Anwendung und ihre klinischen Erfolge an der Freiburger Universitäts-Frauenklinik. Von Prof. Dr. C. J. Gauss und Prof. Dr. A. Lembcke. Mit einem Vorwort Von Prof. Dr. B. Krönig. Price, 15 Marks. Berlin: Urban & Schwarzenberg; New York: Rebman Company, 1912.

Professor Krönig states that on the basis of the abundant proofs accumulated in the treatment of myomas and hemorrhagic metropathies in the last six years at Freiburg, he concludes that these diseases can be cured in nearly all cases in the non-operative way. The Freiburg University hospital has a cure percentage of 100 per cent. with their method of filter close irradiation. The Roentgen doses previously used were too small, and the writers hope that with sufficiently high doses uterine sarcomas can also be cured by deep irradiation. The writers emphasize the fact that the after-effects of Roentgenization are more like those after uterine extirpation than after castration. The first part is devoted to the theoretical bases of Roentgen deep therapy with biological experiments on plants and animals, and an account of the quantitative improvement of the dose of rays active for the human body.

Taschenbuch der Diagnostik und Therapie der Lungentuberkulose. Von Dr. Heinrich Gerhartz, Assistant am. mediz.-poliklin. Institut der Universität Berlin. Mit 48 teils farbigen Abbildungen und 13 teils farbigen Tafeln. Price 5 marks. Berlin and Vienna: Urban & Schwarzenberg; New York: Rebman Company, 1913.

This flexible pocket manual of 200 pages presents a full and at the same time terse account of the modern methods in the diagnosis and treatment of pulmonary tuberculosis. It contains many excellent illustrations showing correct methods of percussion, schematic drawings that serve to elucidate the text, tables of differential diagnosis, lists of European climatic resorts and sanatoria, full page plates, including those of radiographic examinations of the lungs, etc. The tuberculin treatment and the method of inducing artificial pneumothorax are fully described. The book is eminently practical and should prove invaluable to the student and practitioner.

# Society Reports.

## PRACTITIONERS' SOCIETY OF NEW YORK.

*Two Hundred and Fifty-ninth Regular Meeting, Held January 2, 1914.*

THE PRESIDENT, DR. WALTER B. JAMES, IN THE CHAIR.

**Intravenous Injections of Sodium Salicylate in the Treatment of Rheumatic Affections.**—DR. LEWIS A. CONNER read this paper (see page 323).

DR. STARR said he would like to ask whether in general routine practice Dr. Conner preferred salicylate of sodium to any of the other remedies containing salicylic acid which had been introduced. This did not bear on the subject of intravenous injection, but he asked simply for information.

DR. THACHER said he had had no experience with this method, but if the discussion broadened into the general use of salicylates, he could quote the experience of a physician, who, after working up a large practice, had retired on account of ill health. He had acquired a reputation, especially among Chinamen, for curing rheumatism, so much so that they were shipped to him from all parts of North America to be cured. They told him that other doctors were not able to cure them. He said that there was nothing remarkable in his treatment, but that he had suspected that salicylate of sodium was more apt to be adulterated than salicylic acid, and that moreover it was an advantage to have the freshly combined salt; he, therefore, wrote his prescription for a solution of salicylic acid and bicarbonate of sodium, and used large doses. This was his only explanation as to why he was famed for curing rheumatism better than other people did.

DR. ROPER said he had been interested in watching results in some of Dr. Conner's patients. He had attempted to determine the amount of excretion of salicylate by the ferric chloride color test and had been able to demonstrate after five hours that only three to six grains had been eliminated in that time. This was following a 30 grain dose intravenously. After five or six doses that meant that the patient had at least one hundred grains in his system.

DR. BANGS said he was much interested in the remarks about the technique. It was similar to that used in the administration of salvarsan. Had Dr. Conner had any difficulty in finding a vein? The case rarely happened, but sometimes an individual was met with whose veins were so small in the arm or so much encompassed by adipose tissue that it was almost impossible to find a proper vein. In such a case a vein of the leg had to be taken instead in order to find one to take the necessary volume.

DR. DANA said that when he was an interne in Bellevue Hospital the routine treatment of rheumatism was to make a saturated solution of bicarbonate of sodium and add salicylic acid, giving the latter in doses of twenty grains every two hours. The results were very satisfactory. Probably the large amount of fresh salicylate the patients received was the secret of success.

DR. KNAPP said he was particularly interested in what Dr. Conner had said inasmuch as rheumatic conditions of the eye were so frequent. These forms were not associated with articular rheumatism, but usually occurred in patients with a history of muscular rheumatism. In a very serious eye trouble, sympathetic ophthalmia, good results had been obtained by the use of large doses of sodium salicylate. He asked Dr. Conner if he thought that intravenous injection would be of value when such large doses had to be given.

DR. BRANNAN said that when bicarbonate of sodium was combined with the salicylates when first used, years ago, it was probably to obtain the alkaline effect of the soda, not simply to make the salicylates better borne. Did Dr. Conner use this intravenous treatment in private practice?

DR. KENNEDY asked Dr. Conner if this treatment had been used in chorea.

DR. JAMES asked in regard to the general effects, tinnitus, delirium, etc., if the dosage was pushed till these symptoms were obtained. He said he thought a field of usefulness might lie in acute rheumatic affections of the eye. Modern teaching led to the belief that the infections were similar. In the old days it was thought that the drug had to be pushed till they got the physiological effect. If in this case you could get the physiological effect without upsetting the stomach it would be an advantage. In regard to Rosenow's theory of the mutations of the bacterium responsible for the complications of rheumatism, it seemed a slight confirmation of this theory that it was noticed in the clinical study of these cases that if the patient who was subject to repeated attacks of rheumatism was to have a heart complication, he usually got it in the first or second attack; if not, subsequent attacks usually did not harm the heart. This suggested that in this particular patient the type of diplococcus which was present was not the one with an affinity for the heart valve.

DR. CONNER, in answer to Dr. Bangs, said he did not remember experiencing any difficulty in any of the cases referred to, but occasionally one did, in blood cultures or salvarsan injections, find difficulties. Everybody found that. The use of a tiny hypodermic needle made it possible to get into a very small vein. Regarding Dr. Thacher's remarks as to freshly made salts, that it had been claimed that many of the effects experienced were due to impurities in the drug and not to the drug itself, it was a fact that since they had been using the drug in the crystalline form they had had no unpleasant after effects. Before that he had occasionally seen an injection followed by a chill or by vomiting. In answer to Dr. Knapp's question, he thought that if a rapid and powerful effect was desired the intravenous method had a distinct advantage. It was singularly free from uncomfortable effects. In large doses there might be a ringing in the ears and perhaps sweating, but the absence of all prostration and of all stomach discomfort, vomiting, and nausea was very marked. In little children there was always the difficulty of finding a vein, but with older children this should not be a factor.

**"Wry Neck" Deformity from Congenital Nystagmus.**—Dr. M. ALLEN STARR reported this case. He said he had a child brought to his office supposed to be suffering from wry neck. The child was nine years old. She came in holding the head on the right side. She was able to turn the head to the left and there was no characteristics of wry neck. He found she had a bilateral lateral nystagmus, which was evident whenever she turned her eyes or head to the left or attempted to look forward, but when she turned her head to the right it ceased; therefore, in order to bring the eyes to the desired point she had to turn her eyes to the right and therefore her head to the right. She was a bright little girl. After using the eyes much she had slight headache. The case was one of congenital nystagmus and the position assumed by the head was secondary to this, not a true wry neck. Several cases were seen at the clinic every year, but this case was the only one in which a nystagmus persisting to the ninth year had been seen. Usually after the third or fourth year it was outgrown. In adults it was associated with brain tumor or multiple sclerosis. The nystagmus had been present since birth and a physician had told the mother it would be outgrown. He could do nothing to help the condition.

**Case of Metastatic Tumor of the Spinal Cord as First Sympton of Hodgkin's Disease.**—Dr. DANA reported this case. The patient, J. D., single, aged 27, was born of healthy parents. One brother recently developed tuberculosis. Patient had always been a strong, active man with no history of luetic or tubercular infection. About two years ago when he was kicking a football he suddenly lost his balance and fell very heavily on his back. He continued well, however, and went about his business until August, 1912, when he had another fall. Since that time he had had some pain in the back, occasionally running down into the left arm. In November, the pain extended into the shoulder and down the arm into the fingers at times. During December and January, 1913, he had an aching pain and tender spot in the spine about the level of the third dorsal vertebra. He had at this time an *x*-ray taken which was negative; also a von Pirquet test, which was negative. During the following spring and summer he continued to suffer some pain in this same region of the back and arm, especially when he was jarred. In March, 1913, he consulted Dr. Prout of Summit, N. J., who went over him thoroughly, but found no objective symptoms except a trace of albumin in the urine. He was put on iodide of potassium without any good results. A little later he was given a high frequency electric current treatment under which he improved. In April he had an attack of the grippe. During the next two months he improved and seemed to be fairly well until one day in the latter part of June, when he got a bad jolt while riding. After this the pains returned and annoyed him again. In July he had herpes zoster over the area of

the second dorsal nerve on the left side. About the first week in October he noticed a numbness of the left lower extremity and of the left side of the face. A few days later there was difficulty in urination and about this time it was noticed that his pupils were unequal, the left being smaller than the right; also that he chewed more on the left side of the face. Dr. Dana saw him first on November 1, 1913. Patient was a tall, thin man. He was sitting in a chair and was just able to get up from the chair and with help walk a little. This disability had developed quite rapidly within the past few days and even that morning he had been able to go up and down stairs. There was weakness of the flexors of the thighs and legs, but much more of the legs. He had a drop foot in each extremity, almost complete. The knee jerks were equal and exaggerated. There was ankle clonus on each side and the ankle jerks were exaggerated. There was no Babinsky and no plantar response whatever. There was no atrophy and no fibrillary twitchings. There was a distinct absence of pain and temperature sense extending from the toes to about the level of the nipple. The blood examination showed hemoglobin 100 per cent.; red blood cells about 8,000. The spinal fluid examination showed Wassermann negative; cerebrospinal fluid Wassermann, negative; globulin slight; cells about 25 per cmm. He was operated on by Dr. A. S. Taylor, who found an extradural tumor, lying over the upper dorsal segment, extending up and down for several segments. This was removed almost completely. It was sent to Dr. Ewing, who stated that it was a metastatic adenoma and a secondary deposit from some other glandular enlargement, due to Hodgkin's disease. The patient had been examined carefully by Dr. Corwin, the family physician; Dr. Prout, Dr. Foster Kennedy, and himself, and no enlarged glands had been noticed. On the announcement, however, that this was a case of Hodgkin's disease, Dr. Walter B. James was called in consultation. A further examination was made and a small glandular node was found near the clavicle, which was removed by Dr. Hartwell. This was examined and found to present the appearance of Hodgkin's disease.

Dr. James reported that at the request of Dr. Dana he examined the patient and found a diffuse swelling of the base of the neck on both sides, in which certain discreet glands of small size could be found. There was also swelling in the supraclavicular fossa on the left side over which there was dullness and diminution of breathing. The patient had complained of shortness of breath. It seemed to be clear that he was suffering from Hodgkin's disease with an unequal distribution of the glandular enlargement and the physical signs pointed to a fairly extensive mediastinal development of lymphoid tissue. Dr. James advised that a culture of diphtheroid baccillus, which had been isolated from the cultures of Hodgkin's disease by Bunting and Rosenow, be obtained and that a vaccine be made from this and administered. At the time of this report it was too early to determine whether any benefit was obtained or not.

Dr. Peck said he had had a patient a year ago in whom an early and unexpected diagnosis of Hodgkin's disease was made. A young man was admitted complaining of pain in the right iliac fossa. Appendicitis was diagnosed, but upon operation the appendix was normal. A small retroperitoneal gland was removed and found to be typical of Hodgkin's disease. No other glands were discoverable in the body and he made a complete recovery. Three or four months later he returned with other involved glands and symptoms of progressing Hodgkin's disease.

Dr. Starr said he had watched a well-marked case of Hodgkin's disease for three years. During the last six months there was a secondary tumor of the brain. This was manifested by mental symptoms, intense headache, slight exophthalmos, and other symptoms that were distinctly indicative of brain tumor. There were other tumors in the body and the neck. The persistent insomnia was a marked symptom. For nine months the patient had slept very poorly.

**Palliative Treatment of Inoperable Carcinoma of the Bladder.**—Dr. Bangs said he had recently been interested in trying to find out what could be done to relieve a patient with inoperable carcinoma of the bladder. Last April a man of seventy-three had come to him, having all the appearance of having received an extreme shock. He was tremulous, his face grey and drawn, and he was extremely depressed. He said that his case had just been diagnosed as "cancer" of the bladder and that this diagnosis had been corroborated by another prominent diagnostician. The man was frightened to death. He was urinating frequently and blood was always macroscopically present, but there was very little pain. Dr. Bangs cystoscoped him and found a growth occupying the base of the bladder, obscuring the ureters, and it was certainly inoperable. The prostate was enlarged, making cystoscopy difficult and painful. He had marked evidence of chronic nephritis. The question was how was the mental depression and fright to be relieved and what to do for the neoplasm. The patient was told that he had a pimple-like growth which might eventuate in cancer, unless it could be relieved and this could be done. The moral effect was instantaneous. His pulse grew better; his pallor disappeared; his courage returned. A marked grade of cystitis, with fetid urine and great masses of muco-pus, was present. The bladder was treated with irrigations of different kinds and with applications of creolin, the latter to reduce the loss of blood. After having controlled the infection of the bladder the neoplasm was fulgurated every week. The pain of the pressure of the instrument upon the prostate seemed to give him a mild kind of shock, leaving him tremulous and weak. At last he reached a point where he refused to have the fulguration done. The pressure of the cystoscope upon the prostate becoming intolerable, in spite of the use of local anesthetics. The method next used was to give him gas and oxygen for the fulguration treatment. A cystoscope was introduced, by means of which an insulated copper wire was led into the bladder. Through the wire passed an electrical current of extreme high tension and by using a make and break device a spark developed which had an effect upon the tissue exactly where the copper cable was placed. This had worked well, no inconvenience to the patient followed, and the malady was being held in check. This was certainly worth while, for the patient was able to attend to business and share in the ordinary every day life.

Dr. Starr asked if exposure to radium would be beneficial in the bladder.

Dr. Bangs said that Dr. Abbe had told him it was too difficult to use; that it caused great pain, and a better effect was produced by fulguration.

Dr. Abbe said he thought fulguration was better; so far as anything could be good in such an extreme case, that was the best. In the newer methods of using radium it might be tried in time, but at present the methods were not adapted for it.

Dr. Bangs said he had handled a good many cases of tumor of the bladder. By the fulguration method the growth could be cut down and it could be applied on the first reappearance of the tumor. Once having gotten the confidence of the patient the state of the tumor could be watched and its first reappearance checked. Early symptoms must be treated. He had no experience with radium and since this method gave results of which he was sure he preferred to stick to it.

---

## SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

*Twenty-fifth Annual Session, Held at Atlanta, Ga., December 16, 17, and 18, 1913.*

The President, Dr. John Young Brown, St. Louis, Mo., in the Chair.

(*Concluded from page 272.*)

**The President's Address: The Diagnosis and Surgical Technique to Be Employed in the Handling of Acute Abdominal Conditions.**— Dr. John Young Brown of St. Louis considered, (1) gunshot and stab wounds of the abdomen; (2) injuries to abdominal viscera, resulting from severe abdominal contusions; (3) acute intestinal obstruction. Gunshot and stab wounds of the abdomen might be classified under three heads: (1) The simple penetrating wound, or a wound where the knife or bullet penetrated the peritoneal cavity without injury to abdominal viscera. (2) Penetrating and perforating wounds, or wounds where the knife or bullet penetrated the peritoneal cavity and injured either solid or hollow viscera, or both. (3) Complicated wounds, or wounds in which the entrance to the abdominal cavity was made by knife or bullet through the chest, pleura and diaphragm with or without injury to abdominal viscera. It was at times very difficult to differentiate between the simple penetrating wound and the pene-

trating and perforating wounds. Dr. Brown had time and again operated on a patient whose abdomen had been penetrated by a bullet with both a wound of entrance and exit, where no damage to peritoneal viscera was found when the abdomen was opened and careful search for perforations was made. Such wounds gave few or no symptoms. Again, he had operated on many cases in which there was present within multiple bowel perforations, giving no symptoms indicating the serious nature of the injury, for the reason that the patient was not bleeding, as the perforations were in the bloodless portion of the bowel. In the penetrating and perforating wounds, giving no alarming symptoms, delay in exploring was the usual rule, and when the exploration was at last made the patient was found to be suffering from a lethal peritonitis. In contradistinction to the symptoms occurring in the above mentioned cases, they had another type of penetrating and perforating wounds, giving immediate and alarming symptoms. In these cases multiple perforations of the mesentery were present and profuse bleeding occurred at once, bringing about profound symptoms of shock. Such cases demanded immediate operative treatment. Complicated wounds resulting from both knife and bullet were wounds in which the peritoneal cavity was penetrated by the entrance of the bullet or knife through the chest, the abdomen being opened through the diaphragm. While the majority of wounds of this type were readily recognized, he had seen quite a number of such injuries in which the diagnosis was difficult. In all stab and gunshot wounds, where the bullet or knife entered as low as the sixth interspace, irrespective of symptoms, injury to the diaphragm should be suspected and such wounds should be explored.

The surgical treatment of gunshot and stab wounds of the abdomen might be considered under four heads: (1) Preparation and examination of patients. (2) Method of locating injury to peritoneal viscera. (3) Repair of such injuries. (4) After-treatment. In the repair of perforations of the bowel, he had found that they could best be closed either by a purse-string suture or by a through-and-through stitch, supplemented by the Lembert's stitch. In gunshot work, where end-to-end anastomosis was necessary, he much preferred the button to the suture. It had been his invariable custom to drain all gunshot and stab cases where there was extensive soiling of the peritoneal cavity and where severe hemorrhage existed. The drainage was accomplished by means of a glass tube introduced through a stab wound above the pubis and placed at the most dependent portion of the vesicorectal pouch. As to treatment, no hard-and-fast rules could be laid down relative to the treatment of acute obstruction. Too much stress could not be laid on the importance of preparing such cases for operation. As the majority of them came in profoundly toxic and vomiting fecal matter, stomach lavage should invariably be done before the anesthetic was given. The surgical technique should be carried out as rapidly as possible, consistent with thorough work. Dr. Brown said he could not too strongly emphasize the importance of draining the bowel of its highly toxic contents in every case. The after treatment of all of the types of cases considered should be as simple as possible. It was his custom, unless there were special contraindications, to allow such patients to have all the water they desired. Strychnine was never used, and morphine was rarely needed. Proctoclysis, saline solution, being used by the Murphy method, he had found of value. The Fowler position he had practically abandoned as a method of treatment, not only in the types of injuries above described, but in his other acute work.

**Clinical Suggestions Based Upon a Study of Primary, Secondary, and Tertiary or Migratory Epithelial Hyperplasia in the Breast.**—Dr. WILLIAM CARPENTER MACCARTY of Rochester, Minn., said that the plan which suggested itself to him after an extensive experience with the pathological conditions to be dealt with and also an intimate association with the activities of surgeons, seemed to be based upon some known factors relative to the histology of epithelial activities and the fact that surgeons differed regarding the extent of operations necessary in the conditions which had been described. (1) The conditions which were associated with classical signs of carcinoma should be treated radically. (2) The doubtful cases in women near or over thirty-five years of age should have the entire mammary gland removed for immediate examination. If primary or secondary hyperplasia was present nothing more should be done; if tertiary hyperplasia was present a radical operation should be performed. (3) In doubtful cases near or under thirty-five years of age a wide section of the mammary gland, including the pathological conditions, should be removed for extamination. If primary hyperplasia was present nothing more should be done. If secondary hyperplasia was present the rest of the mammary gland should be removed, and if tertiary hyperplasia was present the radical operation should be accomplished. This plan avoided incision of tumors. It removed the possibility of unnecessary radical operation and their physical and psychical embarrassment. It provided for a scientific means of determining more accurately the stage at which cancer might be cured by surgical operations, and the extent of the operation which was necessary to effect such a cure. In the experience of this clinic the removal of the mammary gland preceding an immediate radical operation had not been associated with earlier recurrence than had been found after a primary radical operation. The plan was herewith presented with the realization that it was a conservative experiment which was based upon scientific facts. It was based upon actual research upon each specimen, and was free from the incumbrances of extensive terminology and dogmatism relative to what was and what was not carcinoma.

**End-Results in Operations for Cancer of the Breast.**—Dr. E. S. JUDD of Rochester, Minn., presented a review of the results of operations for mammary cancer in the Mayo clinic from January 1, 1902, to January 1, 1912. This covered 608 cases, of which it was possible to trace the subsequent histories in 514. In all the patients the operations were radical and consisted in the removal of the entire breast, axillary glands and fascia, including the pectoralis major and minor muscles, usually all in one piece. The diagnoses in all of the cases were made from both macroscopic and microscopic evidence. Of the 608 patients, 2 were males, one of whom was alive without recurrence 3 years after the operation, and the other died at the end of 2 years and 8 months from recurrence. The youngest patient was 25 years of age and the oldest 85 years of age. By decades their distribution was as follows: 20-30 years, 13; 30-40, 147; 40-50, 228; 50-60, 147; 60-70, 88; 70-80, 27; 80-90, 1. Of the 13 patients under 30 years of age 5 were alive and well without recurrence. Of the 514 patients of whom the subsequent history is known, 266, or 52 per cent., are known to be dead, though 21 of these died from other causes without clinical signs of recurrence of carcinoma, leaving a balance of 48 per cent. of deaths, probably from cancer, for the entire series. Two hundred and forty-eight of the 514 patients were known to be alive from 2 to 11 4/12 years; 37 of these were known to have recurrences. Of the patients operated on during the years 1902 and 1903, 40 have been traced, 27 were known to be dead from various causes, leaving a percentage of 33 alive without recurrence more than 10 years. Three of those who died lived more than 6 years and died from other causes. Of the 321 patients operated on more than 5 years, 266 were traced; 148 were known to be dead and 106 living, a percentage of 40 who had lived more than 5 years. Six of the living had recurrences at present. Fourteen of those dead had died from other causes than cancer. Of the 510 patients operated on more than 3 years, 437 had been traced; 234 were dead, 191 living, a percentage of 45 of patients living more than 3 years. Twenty-seven of these had recurrences at present. Nineteen of those dead had died from other causes. One case was reported of a patient who died 9 1/12 years after the primary operation from general carcinosis; one from internal metastases without local recurrence 6 5/12 years after operation; and one on whom a secondary operation for recurrence was done 12 years after the primary operation. In this latter case the patient remained well nearly 3 years after the secondary operation. While noting the importance of an immediate radical operation after a diagnosis of carcinoma from a test specimen, Judd noted that the delay in such procedure did not necessarily always mean a bad prognosis. Conversely, he noted that patients in whom there was a very small mammary lesion without determinable glandular involvement might die of early internal metastases. He noted that while edema of the tissues was usually a contraindication to operating, one patient in his series on whom the prognosis was bad because of edema, and yet who was operated on as a palliative measure, was still alive without recurrence 5¼ years later. He noted that cancer in the lactating

breast had usually been rapidly fatal. A very large percentage of the patients heard from had reported that functionally their arms were all right or practically as good as ever. Judd noted that when it had been necessary to destroy one of the motor nerves the function of the arm was much more apt to be impaired. Not over 5 per cent. of the cases had had swelling of the arm. His conclusions were as follows: (1) Results in operations for cancer of the breast were as good if not better than results in operations for cancer elsewhere. (2) The prognosis in younger people who received the benefit of an early operation was better than they had expected. (3) The prognosis was variable in a certain per cent. An extensive external involvement might give a fair prognosis, while a slight external lesion might terminate early from internal metastasis. (4) That metastasis might occur many years after the operation, though in the great majority of instances they would appear in the first few years, if at all. The difference between the percentage of patients living over 3-5 and 10 years was not as great as might be expected, but this was because most patients who died of the disease died within the first 3 or at least the first 5 years. Five years without recurrence meant a very small probability of trouble after that. (5) Comparing these results with those of former years they felt that the results were improving, and that the improvement seemed due to the fact that patients were coming earlier rather than to any improvement or change in the technique.

**Hydrocephalus Internus; Lumbar Drainage by Utilization of a Meningocele Sac as a Drainage Tube.**—Dr. HERBERT P. COLE of Mobile, Ala., stated that the investigations of Leonard Hill disclosed the regulation of cerebrospinal pressure to be due to the venous and lymphatic circulation. The routes of communication, five in number, between the intra- and paracerebral spaces, offered numerous paths for drainage in the event of obstruction to one or more routes. Surgical treatment of hydrocephalus internus, instigated by the failures of medical treatment, dated its inception with the earliest days of surgery. Unfortunately only callosal puncture as advocated by Von Bramen, drainage into the longitudinal sinus after the method of Pays, and the combined subarachnoid and aspiratory procedure of Pussep seemed to be based on a clear interpretation of the anatomical and pathological problems to be dealt with. Numerous other drainage methods to the ventricles direct had been discarded so frequently as to indicate that as yet the operation route of choice had not been obtained. Various surgeons had advocated drainage of suitable cases through the spinal route. Of the different methods that of Cushing seemed to meet with enough success to encourage safe experimentation with this method. By a meningocele sac formed above a spina bifida he attempted to drain a case of hydrocephalus internus through the sac into the lumbar muscles. The case demonstrated that such a drainage would be maintained and was maintained for two weeks without leakage and with relief of the pressure symptoms. The child died on the twenty-sixth day of obstruction in sac. The author concluded that a knowledge of the normal drainage routes was essential to surgical drainage in these cases. Lumbar drainage in suitable cases seemed to offer a better field of experimentation as it was easy of approach and a cleaner field for repeated operations. Drainage by the spinal route might be either subperitoneal or intramuscular. A meningocele sac might be used for a drainage tube, but should be supplemented by an intrasacular firm tube drain. The tender age of the subjects, usually with grave destructive cortical lesions and attendant malnutrition would ever hold the surgical treatment of this condition one of alleviation rather than cure.

**Surgery of the Pancreas.**—Dr. R. C. COFFEY of Portland, Ore., stated that from experimental surgery they had reached the following conclusions: (1) The peritoneum must be brought to the field of operation in all direct pancreatic surgery. (2) Fat necrosis could only occur when the pancreatic fluid was delivered directly into the extraperitoneal fat. (3) Pancreatic fluid was no more dangerous than bile to the peritoneum, provided ample drainage was used to deliver it to the surface at once. (4) The pancreatic duct seemed to depend upon contiguous pancreatic tissue for its nutrition, and, therefore, was not adapted to direct implantation into the intestine. (5) The cut end of the pancreas, carrying an open duct, might be implanted into a loop of intestine with the same assurance that an intestinal anastomosis was made. (6) There was a marked tendency of the pancreatic ducts to reestablish continuity around a gap or an obstacle, provided the pancreatic fluid was temporarily delivered to the surface. (7) If the head of the pancreas was removed and the open end brought to the surface, a pancreatic fistula resulted, which usually closed in a few weeks. The secreting portion of the gland was rapidly destroyed, leaving a fibrous cord which contained many islands of Langerhans. These principles were borne out by the clinical work which had been done. The importance of surgical intervention in traumatic conditions of the pancreas was indicated by the following statistics from Mikulicz: Of forty-five cases of pancreatic injury, there were twenty-one penetrating; twenty-four subcutaneous or penetrating, twelve gunshots, nine stabs; five of the twelve gunshot wounds were operated, three recovered; seven not operated; all died. Seven of the nine stab wounds were operated on and recovered; of twenty-four cases of subcutaneous wounds, thirteen not operated on; all died; of eleven operated, seven recovered. These results corresponded exactly to the principles set forth in the experimental work in that drainage was the only essential feature. Finney and others had resected the middle of the pancreas and brought the cut ends together, using drainage to temporarily take care of the pancreatic juice. Finney's patient made a perfect recovery. Bloodgood had removed the head of the pancreas for cancer, had brought the cut end to the surface, produced a pancreatic fistula, which finally closed. The patient died nine months later from recurrence of cancer in the liver. Post mortem showed destruction of the pancreatic secreting tissues, leaving a fibrous cord which retained the islands of Langerhans. The exact result was the same as observed in experimental work. The writer had removed the tail of the pancreas, as had also Mayo and many others. The duct closed in a very few days, just as occurred in experimental work. The only principle of the experimental work which had not been paralleled by clinical work was the implantation of the pancreas into the intestine in the human. Freeman of Denver had performed that operation by his technique and found it not at all difficult. Unfortunately his patient died as a result of shock. Taking it all together, comparing the clinical work which had been done empirically, and the experimental work which he had performed, their perfect harmony seemed to indicate he had reached a definite basis for pancreatic surgery. Barring the greater anatomical difficulties, we might safely say that surgery of the pancreas was probably on exactly the same basis as surgery of the gall-tracts.

**Pyloric Stenosis in Infants.**—Dr. JAMES F. MITCH-Young Women.—Dr. RANDOLPH WINSLOW of Baltioffered interesting data of distinct diagnostic and pathological value in the development of radiography by means of the bismuth meal before and after operation. Autopsy reported and operation protocols were uniform in their description of a pyloric tumor which was always present, hard and free from adhesions to surrounding parts. The whole pyloric stem was thickened and in cases of long standing the stomach might be dilated and its walls hypertrophied. On inspection the pyloric thickening was found to be due almost entirely to an enormous development of the circular muscle fibers, an increase in both size and number. The lumen varied, but in marked cases with difficulty admitted the finest probe. The etiology was purely speculative, the two leading views being, first, that it was a congenital anomaly which progressed after birth, and, secondly, that there was some primary irritation with consequent spasm and hypertrophy. Kaupe, in 1909, after a careful study of three hundred and forty-six articles bearing on this point, concluded that the etiology was still a mystery. The clinical picture was well established and so characteristic that, having seen one typical example, a second was not likely to be overlooked. The diagnosis in his second case was made by the Sister who had observed the first in its hospital course. Nearly all were described as having been healthy at first: eighty per cent. boys, and the majority first born and breast fed, although Rammstedt had recently reported an operative case which was the third child in one family to have the same condition. In many cases a hard tumor could be palpated at the site of the pylorus, with this observation varying with different reporters from twenty-five to seventy-five per cent. He could not definitely feel a pyloric tumor in any of his three cases examined without an anesthetic. The diagnosis could usually be made on the above signs and

symptoms; but it must be remembered that these varied with the degree of stenosis and that in consideration of the treatment, pyloric spasm without stenosis should, if possible, be excluded. The bismuth radiograph was of great assistance in the differential diagnosis. Surgically, various procedures had been used, such as pylorectomy, divulsion, pyloroplasty, and gastroenterostomy. It was generally conceded that pylorectomy was too formidable. Divulsion offered evident difficulties. The ordinary pyloroplasty was unsatisfactory because of the unyielding structure of the pylorus, and Finney did not consider his operation applicable. In this country posterior gastroenterostomy had been so universally employed as to be looked upon as the operation of choice. Dr. Mitchell, after considering at length the statistics of either medical or surgical treatment, stated that his own experience had been limited to three cases. All came to operation early, only one having reached any degree of emaciation, weighing five pounds, six ounces, a loss of over three pounds since birth. Two were operated at seven weeks and the third at six weeks of age. A posterior gastroenterostomy was done in each instance. The pylorus always presented the typical stony hard, olive shaped tumor with apparently occlusion of the lumen. They were now healthy, normally developing children, three and one-half years, two and one-half years, and eight months after operation. Dr. Mitchell had been able to secure a radiograph of the second case which showed, after two and one-half years, that bismuth was leaving the stomach through the stoma and none by way of the pylorus.

**Excision of the Clavicle and First Rib for Malignant Disease.**—Dr. R. E. Fort of Nashville, Tenn., stated that the immediate mortality of excision of the clavicle was between 16 and 18 per cent. but the end results, or those who died from recurrence, was quite 70 per cent. The results, however, were sufficiently hopeful to make immediate surgical intervention not only justifiable but mandatory. In two cases there was recurrence in four years after operation, in two within 18 months, in one case sarcoma of the femur developed three months after operation, in one case there was local recurrence within six months, in one recurrence was immediate, in one sarcoma recurred in the upper jaw nine months after operation, in three cases recurrence was within three months, in seven recurrence occurred within six months, two were well five years after operation, one case well one year, one case well seven months, one case two years, and a case of his own well six months after operation. Dr. Fort's conclusions are as follows: (1) Primary sarcoma of the clavicle was a rare condition, and the earlier the diagnosis and the more radical the treatment, the better the chances for complete recovery; (2) the writer was of the opinion that partial excision of the clavicle or first rib should not be practised for malignant disease; (3) the danger of local or general metastases was very great, and as division of the bone increased this hazard, excision should be made with the bone intact; (4) because of the favorable results obtained in the few cases of sarcomata of the clavicle and the larger number of sarcomata of the long bone, it was advisable to use the mixed toxins of erysipelas and *Bacillus prodigiosus* for two or three months after operation; (5) under modern aseptic conditions the mortality for excision of the clavicle and excision of the first rib should be comparatively small, and considering the fate of the patients who were denied surgery, the opportunity of relief by surgery was mandatory.

**Congenital Tumors of the Neck.**—Dr. C. E. Caldwell of Cincinnati said that any statement as to the histogenesis of these tumors must be accepted with certain reservations. From the histological findings in a given case they could establish its origin at best only inferentially. More critical study of these tumors, and especially careful histological examination, had shown that not all congenital tumors of the neck were branchiogenic. In estimating the probable nature and origin of such tumors, they must be guided first of all by the history, second by the location, third by the consistency, fourth by the nature of the contents, and finally by the histological elements predominating in the investment of the cyst wall, the interstitial tissue of the wall itself, and the structures in most immediate relation to it. The impossibility of dealing with the whole of this subject in a manner which could be productive of any conclusions worth the while, necessitated limitation to the subject of multilocular serous cysts. From the contributions of Savelli and Florence Sabin, it seemed to Dr. Caldwell that the evidence adduced proved that the lymphatic cavities described by Veau, and the jugular sacs described by Sabin were but different interpretations of the same histological facts, and that in these lymphatic cavities or perhaps more accurately speaking, jugular sacs, they had the fetal anlagen which resulted by arrested evolution, in the multilocular serous cysts, the nature and disposition of which corresponded most accurately with that of these sacs. The absence of a true endothelial investment of the sacs or cysts might be explained on the theory of atrophy from intracystic pressure.

**The Significance of Pain in the Right Iliac Fossa in Young Women.**—Dr. Randolph Winslow of Baltimore stated that he believed that unless the symptoms of appendicitis in young women were frank and clear, the condition was probably something else. Pain and tenderness in the right side, without rigidity, elevation of temperature and leucocytosis was usually not appendicitis. Apparently severe and long-continued pain in the right side in girls was more likely to be neurotic than appendical. Pain might also be reflected from the pelvic organs or some of the other viscera, and the primary seat of the disturbance might be determined by a more careful examination. He thought we frequently operated too hastily on a diagnosis of appendicitis, without considering sufficiently the other possibilities in a case.

**An Instrument and Method for Removing Varicose Veins.**—Dr. Mack Rogers of Birmingham, Ala., stated that the instrument seemed to be an ordinary flexible probe with a handle, but on examination it was found that it was not flexible, but that it was rigid in order to avoid the pockets and sinuses in the walls of the veins and to follow more readily the tortuous course of its lumen. Just in front of the handle there was a distinct shoulder to prevent the ligature from slipping back over the handle. The handle was also very small that it might pass more readily through the lumen of the vein. An ordinary gynecologic standard would afford elevation and support for the foot with the leg extended. A button-hole incision was made about 3 inches below the saphenous opening, transversely to the vessel. The vein was picked up, divided, and the proximal end was ligated and dropped back. The point of the instrument was now inserted into the distal end of the vein and the probe was gently passed down through the lumen of the vessel till the shoulder of the instrument met the cut end of the vein; now a secure ligature was passed around the vein near its cut end causing it to firmly embrace the probe just in front of the shoulder; now the instrument was again gently passed down as far as the tissues around the shoulder or the obstructions in front of the point would permit. The point of the instrument was now elevated beneath the skin, and a second button-hole incision was made over the point of the probe, the same as the first. The vein in the bottom of this incision was again divided and the point of the instrument was forced out through this second opening and was caught by a pair of clamp forceps. While the assistant supported the skin and subcutaneous tissues on each side of the instrument, the operator by successive backward and forward movements of the forceps holding the tip of the probe would gradually strip off the tributaries and surrounding tissue, as the vein was turned inside out on the handle of the instrument as it was dragged down through the lumen of the vessel until it emerged from the second button-hole incision. This process was repeated till all vessels needing it had been removed. Whatever hemorrhage might theoretically occur from the lacerated tributaries was controlled by their own elasticity and the pressure exerted by the hands of the assistant on each side of the instrument at the time. Sometimes the vein broke before it could be removed. This occurred when the tributaries were unusually large and numerous. This also occurred in cases where the walls of the vessels had become thickened and adherent to the surrounding tissues. When this break did occur a new button-hole should be made at the point where the vein gave way and another effort should be made to remove it. If, however, this attempt was not successful, open resection should be resorted to till this particular obstruction had been passed over, then the subcutaneous method should be employed.

**Post-Operative Acute Dilatation of the Stomach.**—Dr. E. P. Hogan of Birmingham, Ala., stated that his limited observation of the prone position had not been satisfactory. In his judgment this position was inconvenient and uncomfortable. He had used the following

treatment in his own cases: (1) The stomach tube was inserted and the stomach was emptied of all contents and irrigated with physiological salt solution until the water returned clear. (2) The patient was placed in the horizontal right latero-prone position. This position was in every way convenient and comfortable. (3) Continuous proctoclysis was given. (4) Everything by mouth was excluded until symptoms were entirely relieved. (5) Strychnine and spartein were given (strychnine, gr. 1/60 or 1/30 and spartein, gr. 2 every four hours). (6) If the patient was not prostrated and was nervous and restless, sufficient morphia was given to produce comfort and sleep. With the above treatment some cases would have no further trouble. In others it might be necessary to repeat the washing of the stomach and morphine some four to twelve hours later. It should be repeated as often as indicated.

**Intestinal Resection; Successful Removal of More Than Twelve Feet of Bowel with Observations on the Subsequent Metabolism.**—Dr. RAYMOND C. TURCK of Jacksonville, Fla., reported the successful removal of 10 feet 10¾ inches of ileum, together with the cecum, ascending and part of the transverse colon because of dense adhesions, numerous partial obstructions, fecal fistula, and multiple sinuses. The work was done in three stages. Serious metabolic disturbances and diarrhea followed. Studies of the metabolic processes, eight months after the ileum resection, showed that a probable compensatory hyperplasia of intestine with consequent compensatory production of enterokinase had taken place, enough, with a regulated diet to thoroughly digest and assimilate carbohydrates and a moderate amount of fats, but not enough to fully care for proteids. A measured diet, adjusted according to caloric values, and thorough metabolic examination of feces controlled the diarrhea and caused a decided gain in strength and weight. Medication had no effect upon the diarrhea. Turck believed that, since the small intestine varied from 15 to 25 feet in length, no absolute rule could be laid down as to the amount of gut that might be removed with safety, and that reports of extensive resections were of no especial scientific value unless there could be shown in that particular individual the total length of intestine. Short-circuiting, when possible, was preferable to resection, particularly if the absorption area in the ileum was involved, and in cases of necessary extensive resection it was suggested that Fantino's plan of creating a vicious circle in the remaining segment of gut be tried.

**The Conservative Treatment of Undescended Testicle.**—Dr. ALEXIUS MCGLANNAN of Baltimore stated that the important questions to be decided regarding the conservative treatment of undescended testicle were, first, Was the non-descended testicle worth saving? Second, Was it technically possible to bring such a testicle into the scrotum in a manner that would preserve its vitality? A study of 16 cases operated upon by Dr. McGlannan, the histology of seven undescended testicles removed by several other operators, together with the literature on the subject, proved that an affirmative answer should be given to both questions. The histology of undescended testicle permitted the separation of these glands into four groups: (1) Those with few signs of disturbed development. (2) Those with marked disturbance (infantile type). (3) Those showing senile retrogression. (4) Those consisting largely of edematous fibrous tissue. The testicle might be arrested in the groin at the pubes, or remain in the abdomen. The vas and its vessels, as well as the spermatic vessels, might descend farther than the testicle, or might be in the canal or scrotum, while the testicle remained in the abdomen. The vessels and the testicle might be contained in a peritoneal fold, practically a mesorchium. In many cases simple division of adhesions in the canal, and straightening of the vessels, would permit the transplantation into the scrotum. When this failed, the shortened spermatic vessels were nearly always found to be the obstacle. Under such circumstances these vessels should be divided, as advised by Bevan, depending on the deferential vessels for the nutrition of the testicle. The factor of safety in the testicular blood supply was great enough to give a sufficient circulation after this maneuver. Unless the shortened structures be lengthened the transplantation would fail. No amount of fixation in the scrotum, or fixation by plastics to the thigh would prevent retraction on the shortened cord. The best age for operating was at about 10 years, so that the development of secondary sexual characteristics might not be retarded. In adults nearly one-half the removed undescended testicles contained tubules showing active spermatogenesis, the remainder were either infantile or senile. Senile atrophy occurred earlier, and progressed more rapidly, than in the normally descended gland. That the undescended gland might be transplanted without loss of function was shown by the result in one of the cases in the series now reported. Both testicles were undescended in a man of 30. Both were transplanted after division of the spermatic vessels. Eighteen months after the operation this patient became the father of a healthy child. In all sixteen cases hernia was a complication. Malignant tumors, and inflammatory disease of the testicle were absent from the series. Ten patients had been traced from 7 years to 3 months after operation. All were cured; the hernias had not recurred, and the testicles remained securely in the scrotum.

**Experience with a Method of Immediate Repair of Perineal Lacerations.**—Dr. GREER BAUGHMAN of Richmond, Va., stated that the plan devised by Dr. Charles R. Robins in 1909, and used in the series of cases, was as follows: The procedure was simple; the most important things to consider were a good light and a good exposure of the torn area. The patient was placed on her back with the thighs flexed on left abdomen and held in place with a suitable support like the Robb-Kelly strap. The vagina was cleansed of clots and the upper part of the vagina packed with sterile gauze or cotton, so as to make the field of operation as bloodless as possible. Then a good light was thrown into the vagina. Robins recommeded sewing the mucous membrane and submucous fascia of the vagina to the mucous membrane and submucous fascia of the opposite side of the tear with a continuous chromicized catgut suture. Care must be taken not to catch the muscles with the suture. The suture began at the upper part of the tear in the vagina and was continued down toward the vulva, uniting the mucous membrane and fascia with a continuous running suture, the operator trying to match the part of one side to that from which it had been torn. This restored the shape of the vagina (the vaginal sheath). After the vulva had been reached, the suture and needle were laid in the vagina to be used later to unite the skin with a continuous suture. If there happened to be another tear in the vaginal sulcus or median line, which was almost always the case after the use of forceps, that tear was sewed, the mucous membrane and fascia to the mucous membrane and fascia of the opposite side, and when the vulva was reached, the suture was temporarily laid aside. Then the crown sutures of silkworm gut were put in from the skin surface just as was usually done, slanting downward and backward; but the rectum should not be entered, as sometimes happened, unless one felt in the rectum with a gloved hand. It was well to pull the wound well forward with the sutures before tying, to see the perineum was well cared for; then they were tied. The catgut suture that was stopped at the opening of the vulva was then picked up with a continuous suture, the denuded surfaces were brought into apposition and the suture continued down the skin. If the rectum had been torn, the sphincter ani might be caught and brought together by a silkworm gut suture introduced in the skin just above the rectum, passing through the muscle and out at the other side through the skin. A similar suture just above the mucous membrane of the rectum, introduced from the skin, passing around the tear in the rectum and coming out on the skin of the opposite side, would draw the mucous membrane down like purse-string. When the sewing was aided by a good light the sewing was well-nigh perfect.

**Catgut as a Skin Suture.**—Dr. WILLIAM PERRIN NICOLSON of Atlanta, Ga., stated that the use of catgut as a skin suture had been opposed and rejected by many surgeons on account of objections which could be overcome. It was claimed that it became a safe suture just in proportion as the integrity of the skin was not damaged by excessive efforts at disinfection, and that a skin simply prepared would handle catgut as safely as any form of suture. The ideal condition surrounding an operative wound was that it should be made under aseptic conditions and closed with a suture which could in the end be disposed of by the tissues, thus permitting the original dressing to remain in place until healing was complete. Such a condition could only occur under the use of catgut sutures in the skin. The two objections used against the use of such a suture had been, first, that the animal suture became

a good culture medium for the bacteria in the skin, and, second, that too early absorption might permit the wound edges to gap before healing had taken place. It was claimed that the first condition was largely overcome by simple cleansing of the skin, which consisted of washing with soap and water and alcohol, and afterward applying tincture of iodine upon the perfectly dry skin, and this permitted to remain for about two minutes, after which it was washed off with alcohol. The second was overcome by the use of twenty-day chromic catgut. The size employed was the OO under ordinary conditions, and perhaps a little larger size where there was more strain upon the wound. The method of closing wounds advocated was the continuous running suture placed at intervals of from one-half to three-fourths of an inch and passing beneath the skin into the subcutaneous fat, which permitted the wound line to fall into perfect apposition, while at the same time the edges could be pulled apart at any point between the stitches. This permitted of drainage directly between the wound edges into the dressings, doing away with the necessity for a drain, and the blood serum drying in the gauze next to the wound made a perfect aseptic covering, practically impervious to air and water. Such wounds might be left without disturbance until healing was complete, when the dressing was removed permanently. All classes of wounds, including scalp wounds, hernia operations, breast amputations, kidney operations, were closed thus with chromic catgut and left until healing was complete. The catgut employed was that sterilized without chemicals, as it had been found that those sutures which contained iodine and mercurial salts had proved irritating to the tissues immediately surrounding the suture. In conclusion, it was claimed that such a condition removed the dread that every patient naturally had of the removal of stitches and change of dressings, and did away with the danger of infection, however remote, which attended upon exposure of the wound for the purpose of dressing and removing sutures.

**Thrombosis of the Mesenteric Vessels in a Scrotal Hernia.**—Dr. EDWARD A. BALLOCH of Washington, D. C., said that he thought that he had exhausted the possibilities in the way of complications in hernia until the following case added one more to the list. The subject of this report was a man, 45 years of age, who entered the hospital on February 7, 1913. He was an expressman by occupation and stated that he had had an irreducible right inguinal hernia for several years which had never given him any trouble until a few days before admission, when, after lifting a heavy weight, he had suffered from pain and discomfort for which he sought relief. At the time of admission his pulse was 116 and his temperature 99° F. Examination showed a right scrotal hernia, 15 x 8 cm., irreducible. Tympanites was present in the upper part of the hernia, while the lower half was dull on percussion, and had a doughy, semielastic feel. The abdomen was typanitic and waves of peristalsis could be seen passing across it from left to right, going down into the hernial sac. This fact was demonstrated several times. There was no vomiting or other sign of obstruction at any time. The notes showed that he felt comfortable and slept well. He took the ordinary ward diet without apparent discomfort. The dull area was aspirated with a hypodermic needle and bloody fluid obtained. Diagnosis, hernia with associated hematocele. It was thought that the lifting had caused the rupture of a vessel within the sac, causing the hematocele. Operation, February 10. When the sac was opened it was found that the dull area corresponded to a portion of the small intestine from which the circulation had been cut off for a distance of a half meter. This portion of the gut was pultaceous, and verging on gangrene. The ileum was enormously distended, but its walls were in a state of chronic thickening, showing that this condition was an old one and not due to acute distention. There was no constriction at either ring, and the distended intestine passed freely into the upper part of the sac, thus eliminating strangulation as a factor in the case. The gut was adherent to the wall of the sac, which accounted for the irreducibility of the hernia. The affected gut was removed with a good margin so that the proximal and distal ends of the gut were of nearly equal diameter, and an end-to-end anastomosis done. The patient did well for a few days, when a fecal fistula developed at the site of the operation wound, which was followed, four days later, by a peritonitis, which caused death on February 25, two weeks after operation. This case was interesting to Dr. Balloch for several reasons: (1) The entire absence of signs of obstruction was noteworthy. The tympanites, the patient stated, had been present for a year or more, and the fact that the peristaltic waves could be seen to pass into the upper part of the hernial sac seemed to exclude the possibility of strangulation. The entire absence of vomiting, or even of nausea in this case, he was utterly at a loss to explain, unless it be assumed that the thrombosis did not occlude the lumen of the gut sufficiently to cause obstruction. It was unfortunate in more ways than one, as it led him to defer operation for two days, greatly to the patient's detriment. (2) The association of tympanites with a dull area, the former of long standing and latter recent, together with the history of its appearance after lifting a heavy weight, seemed to him to indicate an acute effusion of blood into the hernial sac, and to make the diagnosis of associated hematocele a rational one. (3) The method of anastomosis used in this case was not suited to the conditions present. At the time of operation the end-to-end anastomosis seemed warrantable, but the author was not convinced that a side-to-side union would have been much better in this particular case.

The following papers were also read: "Hysterectomy," by Dr. A. C. SCOTT, Temple, Texas; "A Study of the Causes of Unsatisfactory Results Following Operation on the Biliary Tract," by Dr. J. M. T. FINNEY, Baltimore; "Ultimate Results in Eight Cases of Colectomy for Fecal Stasis," by Dr. JOHN G. CLARK, Philadelphia; "Heredity in Bone Lesions, with the Report of an Unusual Family History," by Dr. JOSEPH RANSOHOFF, Cincinnati; "Ankylosis of the Jaw," by Dr. V. P. BLAIR, St. Louis, Mo.

**Operative Treatment of Ankolysis of the Mandible.**—Dr. V. P. BLAIR of St. Louis, Mo., said that his observations convinced him that practically all of these cases of ankylosis could be permanently relieved. The ages varied, his youngest operated case being five years old and the oldest case treated being sixty. In nearly 50 per cent. of all reported cases the most common cause was trauma by a blow or fall on the chin. Next to injury came scarlet fever, accounting for one-fifth of all cases. From the reported cases bony ankylosis would be inferred as the cause in the majority of the cases, but his were mostly fibroosseous. The development of the ankylosis had in his cases been gradual. Following the injury or arthritis the opening became gradually limited and decreased until there was complete or almost complete closure. The result of forceful dilation were only temporary. The chief symptom was the inability to freely open the mouth, which latter was apt to be foul and masses of tartar covered the molars. In a somewhat close unilateral fibrous ankylosis, as the mouth opened, the chin deviated to the ankylosed side. He distinguished between cases where the joint was affected directly and those in which the limitation was due to binding scars in the cheek; though an Esmarch operation was designed to relieve both conditions. Simple division or excision of the cheek bands had not been efficacious, the bands soon united again or new scar formed. For the permanent correction of scar bands in the cheek, it was most reasonable to excise these bands and replace them with epithelial tissue. Where the mucous lining of the mouth was deficient, he had with satisfactory results, transplanted a skin flap from the neck left attached by a pedicle, and brought into the mouth through an incision in the lower fornix of the cheek. The flap was sutured in place and about two weeks later the pedicle was cut and the defect in the neck repaired. For ankylosis directly affecting the joint, an excision of the joint or the removal of a section from the body of the ramus was necessary. A considerable piece must be removed or some material (he used subcutaneous temporal fascia) must be interposed to prevent the cut ends reuniting. His incision, which differed from those presented elsewhere, had the advantage of being within the hair and allowed the making of a suitable flap of fat tissue for the construction of the new joint. A skin flap, with very little subcutaneous tissue, was turned downward and forward. A similar flap was made of subcutaneous tissue down to the temporal fascia, the parotid gland containing the branches of the seventh nerve, and the masseter muscle were stripped downward *en masse*, and the condyle, coronoid process and upper part of the ramus were removed. The fat flap was sutured to the now exposed internal pterygoid muscle so that it rested between the cut portions of bone. Though it caused the patient some discomfort, he preferred to dress the mouth open for one week. A report of 14 cases of the

author's and 194 drawn from the literature were appended.

Officers.—*President*, Dr. John Wesley Long, Greensboro, N. C.; *Vice-Presidents*, Drs. A. C. Scott, Temple, Tex., and James F. Mitchell, Washington, D. C.; *Secretary*, Dr. William D. Haggard, Nashville, Tenn., reelected; *Treasurer*, Dr. Le Grand Guerry, Columbia, S. C., reelected.

Asheville, N. C., was selected as the place for holding the next meeting.

## State Medical Licensing Boards.

### STATE BOARD EXAMINATION QUESTIONS.

LOUISIANA STATE BOARD OF MEDICAL EXAMINERS.

*October 27, 28, and 29, 1913.*

ANATOMY.

1. Name boundaries, anterior and posterior, of axilla.
2. Describe the thoracic duct.
3. Give origin, and structures supplied by the glossopharyngeal nerve.
4. Describe the Y- or iliofemoral ligament.
5. What is connective tissue? Where is it found?
6. Name ligaments of ankle joint.
7. Describe the pleura.
8. Describe the arteries and veins passing to and from the kidney.
9. Give component parts of spermatic cord.
10. Describe the relations of the peritoneum to the bladder.

PHYSIOLOGY.

1. What is invertin, and what part does it play in digestion?
2. What is an internal secretion? Name the more important organs concerned in the process of internal secretion.
3. What are the principal waste products of metabolism and through what channels are they excreted?
4. What are the average proportions of the principal constituents of normal human milk?
5. What kind of nerve impulses are carried through efferent and afferent nerve fibers?
6. What is the result of injury to, or removal of, the semi-circular canals?
7. Name the nerves concerned in the constriction and in the dilatation of the pupil of the eye.
8. State briefly what is understood by diapedesis and phagocytosis.
9. What factors are concerned in the second sound of the heart and where is this sound best heard?
10. Relative to external respiration, state briefly what is understood by (*a*) tidal air, (*b*) complemental air, (*c*) reserve air, (*d*) residual air.

CHEMISTRY.

1. What are the principal allotropic forms of carbon?
2. How does carbon dioxide act as a poison?
3. What is an unorganized or soluble ferment?
4. Name the soluble ferments of the body.
5. What are the tests for starch?
6. What caution should be observed in testing urine for sugar?
7. What are ptomaines, and name some of the best known ptomaines.
8. What is the principal salt of silver used in medicine, and what are the properties of this salt?
9. What are fats, and name the principal animal fats?
10. (*a*) Is elementary arsenic poisonous? (*b*) How does arsenic prove poisonous? (*c*) Which is the most common poisonous compound of arsenic?

PHYSICAL DIAGNOSIS.

1. What are the types of normal respiration, and what conditions would cause alterations of same?
2. What conditions influence the production and variation of pitch?
3. Define dyspnea, and state the types and causes of same.
4. Summarize the points of differentiation between pleuritic friction sounds and bronchitis.
5. Describe the natural heart sounds, and the causes of each.
6. Describe the characteristics and significance of the various kinds of arterial pulse.
7. What are the physical signs of pericarditis with effusion.
8. Differentiate cardiac hypertrophy and cardiac dilatation.
9. Give the physical signs of combined aortic and mitral insufficiency.
10. Describe the physical signs of ascites and those of cystic disease of the ovary.

### ANSWERS.

ANATOMY.

1. The axilla is *bounded: Anteriorly*, by the clavicle, Subclavius, Pectoralis major, costocoracoid membrane, Pectoralis minor; *posteriorly*, by the Subscapularis, Teres major, and Latissimus dorsi.

2. The *thoracic duct* extends from the second lumbar vertebra, where it commences by a dilatation, the *receptaculum chyli*, to junction of left internal jugular with left subclavian vein. The abdominal part is placed on the front of the body of the second lumbar vertebra, behind and to the right side of the aorta and on the inner side of the right crus; it then enters the thorax through aortic opening, on the right side of aorta, lying between it and the vena azygos major, and passes upward to right of aorta on right intercostal vessels. Opposite the fourth dorsal vertebra it passes to the left behind arch, and runs along the left side of the esophagus, behind the left common carotid artery. At the level of the seventh cervical vertebra it turns outward, and, passing behind left internal jugular and crossing first part of left subclavian artery, arches over the apex of the left pleura to open at the angle of union of the left internal jugular and left subclavian veins.—(From *Aids to Anatomy.*)

3. GLOSSOPHARYNGEAL NERVE. *Origin:* The upper part of the medulla oblongata, in the groove between the olive and restiform body; its deep origin is from the floor of the fourth ventricle. It *supplies:* Pharynx, fauces, and tonsils with general sensation; the posterior part of the tongue with the special sense of taste; it is also the motor nerve to the Stylopharyngeus muscle.

4. The *iliofemoral* or *Y-ligament* is connected with the capsule of the hip joint. It is attached above to the anterior inferior spine of the ilium; below it divides into two bands which are attached to the two ends of the intertrochanteric line.

5. *Connective tissue* is a general name given to several forms of tissue which support and connect the other tissues of the body; it is composed of cells and intercellular material. It is found in bone, periosteum, cartilage, perichondrium, the investing membrane of glands, the covering sheaths of nerves, arteries, veins, ligaments, basement membranes, tendons, and practically all viscera.

6. The *ligaments of the ankle-joint* are: Anterior, posterior, internal lateral (or deltoid), and external lateral ligaments.

7. "The *pleuræ* are two serous sacs enclosing and investing the lungs. Each pleura consists of a visceral and parietal layer. The *visceral* portion covers the lungs, and the *parietal* layer lines the inner surface of the chest walls, the upper surface of the diaphragm, and the sides of the pericardium. The visceral and parietal layers of the corresponding pleura become continuous in front and behind the root of the lung; and below the root a fold, the *ligamentum latum pulmonis*, extends downward along the inner surface of the lung to the diaphragm. The mediastina are formed by the visceral layers of each side approaching one another toward the median line."—(*Aids to Anatomy.*)

8. The *renal arteries* arise from the abdominal aorta, just below the superior mesenteric artery; they pass out at right angles to the aorta, and cross the crus of the diaphragm. The right is longer than the left, passes behind the inferior vena cava, the right renal vein, the head of the pancreas and the duodenum. The left passes behind the left renal vein, the body of the pancreas, and is crossed by the inferior mesenteric vein. Before reaching the kidney each artery divides into four or five branches.

The *renal veins* lie in front of the renal arteries; the left is longer than the right and receives the left spermatic vein. They both open into the inferior vena cava.

9. The *spermatic cord* consists of the vas deferens with artery to the vas, spermatic artery, and pampiniform plexus of veins forming spermatic vein above, sympathetic nerves, the cremasteric artery, the genital

branch of the genitocrural nerve, lymphatics, together with some areolar tissue; it extends from the internal abdominal ring to the testis, passing in its course along inguinal canal, from which it emerges by the external abdominal ring, and thence in front of the pubes to the scrotum. The vas deferens is placed at the back of the cord.

10. *Relation of peritoneum to the bladder:* The superior surface of the bladder is entirely covered by peritoneum, so is the posterior surface as far down as the base of the bladder. The inferior surface is uncovered by peritoneum. The lateral surfaces are covered by peritoneum in their upper part. The anterior surface is covered by peritoneum in the upper part, and not in the lower part; the extent of peritoneal covering depends, here, on the degree of distention of the bladder.

PHYSIOLOGY.

1. *Invertin* is an enzyme produced in the mucous membrane of the small intestine; it turns saccharose, maltose and levulose (which are non-assimilable) into dextrose and levulose (which can be absorbed).

2. *Internal secretions:* It is generally held now that the glandular organs, chiefly the pancreas, liver, and the ductless glands, produce a secretion, peculiar in each case to the particular gland producing it, and which is supposed to be given off to the blood or lymph, and to have some peculiar value in the general metabolism of the body. Such secretions are called internal secretions, in contradistinction to the previously known secretions, which are carried off by a duct, and are known as external secretions. Very little is definitely known of these internal secretions, but much work is being done on the subject.

Internal secretions are produced by the liver, pancreas, ovaries, testes, thyroids, parathyroids, spleen, suprarenals, pituitary body, and by the fetus.

3. The *principal waste products of metabolism* are: Water, carbon dioxide, nitrogen, and various solids. They are excreted by the kidneys, skin, lungs, and intestines.

4. Normal human milk consists of about 88 per cent. of water and about 12 per cent. of solids. These latter are, approximately: proteins, 2 per cent.; fats, 3 to 4 per cent.; sugar, 6 per cent.; and inorganic salts, about 0.3 per cent.

5. *Efferent nerve fibers* may carry the following kinds of impulses: Motor, vasomotor, accelerator, inhibitory, secretory, and trophic. *Afferent nerve fibers* may carry: Sensory, special sense, thermic, and inhibitory impulses.

6. "The semicircular canals are, through the vestibular nerve and the cerebellum, the most important agents in the preservation of equilibrium. When in a pigeon the horizontal canals are divided, the head moves from left to right and from right to left, with nystagmus and a tendency to revolve on its vertical axis. When the inferior vertical or posterior canals are divided the head oscillates from front to rear; the animal has a tendency to fall backward. A section of the superior vertical canal causes the head to oscillate from front to rear, with a tendency to fall forward. A section of all the canals is followed by contortions of the most bizarre nature. After a destruction of all the canals the animal cannot maintain his equilibrium. Similar phenomena have been observed in man in disease of the semicircular canals, known as Menière's vertigo. In the fixed position of the head there is equilibrium, but with each movement the varying tension of the liquid in the ampulla changes and irritates the hair-cells." (Ott's *Physiology.*)

7. *Contraction of the pupil of the eye* is caused by stimulation of the third cranial nerve, or by section of the cervical sympathetic. *Dilatation of the pupil* is caused by section of the third cranial nerve, or by stimulation of the cervical sympathetic.

8. *Diapedesis* means the passing of the red-blood corpuscles through the unbroken wall of a blood-vessel; it is also applied to the similar passage of the white blood corpuscles through the vessel wall.

*Phagocytosis* is the process by which the cells of the body (notably some of the white blood cells) ingest certain other cells and bacteria.

9. The second sound of the heart is caused by the vibration due to the closure of the semilunar valves. It is best heard over the base of the heart.

10. *Tidal air* is the air which is constantly passing in and out of the lungs during ordinary calm respiration. It measures about 30 cubic inches.

*Complemental air* is the air which can be taken in beyond what is normally inspired in ordinary breathing. It measures about 100 cubic inches.

*Supplemental air,* or *reserve air,* is the air which can be expelled at an extraordinary expiration. It measures about 100 cubic inches.

*Residual air* is the air which still remains in the lungs after the deepest expirations. It measures about 100 cubic inches.

CHEMISTRY.

1. The principal allotropic forms of carbon are the diamond, graphite, and coal.

2. Carbon dioxide is not a poison. It kills by causing spasm of the glottis; it is irrespirable.

3. *Soluble ferments,* or *enzymes,* are hypothetical substances produced by living cells, and which by their mere presence in a suitable medium cause certain definite and characteristic changes.

4. The soluble ferments, or enzymes, of the body are: Ptyalin, pepsin, trypsin, steapsin, amylopsin, lipase, enterokinase, invertin, erepsin, prothrombin, amylase, maltase, glucase, and lipase.

5. *Tests for starch:* (1) The addition of iodine causes a blue color to appear. (2) By the action of diastase four dextrins are produced: Erythrodextrin, which is colored red by iodine; achroodextrin, which is not colored by iodine.

6. Before urine is tested for sugar, any albumin (if present) must be removed.

7. *Ptomaines* are basic, nitrogenous organic compounds, produced from protein material by the bacteria which cause putrefaction.

*Some well-known ptomaines:* Tyrotoxicon, spasmotoxin, tetanotoxin, tetanin, muscarin, cholin, neurin, cadaverin, putrescin.

8. Silver nitrate, $AgNO_3$, is the principal salt of silver used in medicine. It occurs in crystals which are soluble in water; such solution is colorless and neutral; but in the presence of organic matter it turns black in the sunlight.

9. *Fats* are mixtures of certain triglycerides, chiefly tripalmitin, tristearin and triolein.

10. *Elementary arsenic* is not poisonous as long as it remains elementary arsenic. But on exposure to the air and on becoming oxidized, arsenic becomes poisonous. The most common poisonous compounds of arsenic are arsenic trioxide, and Paris green.

PHYSICAL DIAGNOSIS.

1. The *types of normal respiration* are: Vesicular, bronchial, and bronchovesicular. Alterations may be caused by: Pulmonary tuberculosis, lobar pneumonia, pleuritic effusion, thoracic aneurysm, and mediastinal tumors.

2. The *pitch* of a percussion-note is high over areas of consolidation; increased volume causes a low pitched note, and diminished volume gives a high pitch. A forcible expiration lowers the pitch. Higher pitch may denote tuberculosis, pneumonia, gangrene or tumor of the lung.

3. *Dyspnea* is the term used to denote difficult or impaired breathing. It may be inspiratory, expiratory, or both; and there may be an increase in frequency, or depth, or both, of the respirations. It is attended by varying degrees of distress, and when its severity requires the patient to sit up constantly it is called orthopnea. Dyspnea may be due to obstruction of the air-passages, pressure upon the respiratory system from without by tumors, and distention of abdomen, diseases of the lungs and pleura, heart disease, asthma, anemia, or paralysis of muscles of respiration as the result of hemorrhage, tumors, or degeneration of the respiratory center in the medulla or toxic agents in the blood. It may be *inspiratory* when it results from obstruction as in foreign bodies in the larynx or trachea, or it may be *expiratory* as in emphysema, or bronchial asthma. A combination is the more frequent condition. In all forms of dyspnea it is important to determine whether the shortness of breath bears any relation to exertion. Dyspnea independent of exertion is a serious condition and is symptomatic of severe cardiac and pulmonary disease. Dyspnea dependent upon exertion is less serious and is observed in health, simple debility, anemia, obesity and somewhat moderate cardiac debility. Dyspnea with slow or normal breathing is observed in diabetic coma, and again the breathing may be slow and stertorous, as in coma of central origin. Rapid respiration occurs in inflammatory pulmonary disease, pleurisy, painful affections of the chest muscles, heart

disease, fever, hysteria, toxic conditions affecting the respiratory centers, anemia, and morbid conditions at the base of the brain. Dyspnea may be constant or paroxysmal. Constant dyspnea is seen in asthma and cardiac affections. It may follow exertion in various central or reflex conditions. It is most marked at night. (From Hughes' *Practice of Medicine.*)

4. Pleuritic friction sounds seem to be near the surface, they have a creaking or rubbing character, are generally localized, are not modified by coughing, and seem to be intensified by pressure of the stethoscope. In bronchitis there may be râles, but they have none of the above-mentioned characteristics.

5. There are two normal heart sounds which follow in quick succession, and are succeeded by a pause. The first, or systolic, sound is dull and somewhat prolonged, the second, or diastolic, sound is sharper and shorter. The sounds may be expressed by the syllables—*lubb—dup.*

The first sound is heard best at the apex beat in the fifth left intercostal space; the second sound is heard best over the second right costal cartilage.

The *causes* producing the *first* sound of the heart are not definitely ascertained; the following are supposed to be causatory factors: (1) The vibration and closure of the auriculoventricular valves, (2) the muscular sound produced by the contraction of the ventricles, and (3) the cardiac impulse against the chest wall.

The *second* sound is caused by the vibration due to the closure of the semilunar valves.

6. Varieties of pulse. *Tachycardia* may be the result of a heavy meal, fear, exertion, excitement, fever, heart disease, exophthalmic goiter, cerebral disturbances. *Bradycardia* may be observed in jaundice, atheroma, cerebral disturbances, aortic stenosis, fatty degeneration of the heart. *Intermittent pulse* may be found associated with myocardial disease, dyspepsia, excitement, excessive use of tobacco or coffee, etc. *Irregular pulse,* found in organic heart disease, especially mitral regurgitation. *Dicrotic pulse,* found in typhoid fever and other adynamic conditions. *Corrigan's pulse,* found in aortic regurgitation. *Hard pulse,* found in arteriosclerosis, plethora, apoplexy, chronic nephritis, anemia. *Soft pulse,* found in collapse, typhoid, cardiac degeneration.

7. *Physical signs of pericarditis with effusion.* "(1) Marked increase of the cardiac dulness; (2) displacement of the apex beat; (3) muffling of the heart sounds; (4) displacement of other organs (if effusion be great). The shape of the dulness is characteristic. It is conical, the apex of the cone being truncated, and situated at the level of the second rib, owing to the close attachment of the pericardium to the great vessels at this point. The apex beat is generally pushed upward, and to the left. It lies, when it is palpable at all, distinctly within the left border of cardiac dulness, not, as in enlargement due to valvular disease, in close relationship to it. The marked distention of the pericardial sac surrounds the heart with fluid, and causes a dulness extending much beyond the limits of the organ itself. The amount of bulging and displacement of organs will, of course, vary with the amount of fluid present. As resolution takes place the friction returns, and may be very coarse in character. Muffling of the heart sounds is not always present, and is not entirely due to the presence of fluid, for the fetal heart is quite distinctly heard through an amount of fluid greater than is usually present in pericarditis. The muffling is therefore due mainly to weakness of the cardiac muscle from accompanying myocarditis, although where the quantity of fluid is very great, in serous and chronic pericarditis, this may in part account for it."—(Wheeler and Jack's *Handbook of Medicine.*)

8. Cardiac hypertrophy: "*Inspection* reveals fullness or prominence of the precordium with a distinct impulse. *Palpation* detects the impulse one or two intercostal spaces lower down and to the left. It is stronger and more or less diffused—the heaving impulse. *Percussion* determines an increase in the area of cardiac dullness vertically and transversely on the left side of the sternum, unless the right ventricle is also hypertrophied, when the cardiac dullness is increased to the right of the sternum. *Auscultation* in simple hypertrophy without any valvular changes detects a loud first sound of a somewhat metallic quality, the second sound being strongly accentuated. In the presence of valvular disease the characteristic murmurs are heard in addition."

Cardiac dilatation: "*Inspection* detects enlargement and distention of the superficial veins and an indistinct, often wavy and diffused, cardiac impulse. If tricuspid regurgitation is present jugular pulsation will be observed. *Palpation* confirms inspection; the impulse is feeble, irregular, and heaving. *Percussion* serves to determine extension of the area of cardiac dullness transversely and especially toward the right side. *Auscultation* in the presence of valvular lesions reveals characteristic murmurs. If there are no valvular lesions the cardiac sounds are weaker than normal and the first sound is sharper in quality than usual."—(Hughes' *Practice of Medicine.*)

9. In *combined aortic and mitral insufficiency* there will be found an enlarged left ventricle; a systolic murmur heard loudest over the apex, and transmitted to the left axilla; a diastolic murmur heard loudest at the right border of the sternum at the level of the third intercostal space, and conducted in a downward direction.

10.

| ASCITES. | OVARIAN CYST. |
|---|---|
| Enlargement comparatively sudden. | Gradual. |
| Face puffy; color waxy; early anemia. | Facies ovariana. Anemia absent, or later. |
| Patient on back, enlargement symmetrical; flat in front. | Asymmetrical until tumor is quite large; prominent in front. |
| Sitting up, abdomen bulges below. | No appreciable change. |
| Navel prominent and thinned. | Navel usually unchanged. |
| Fluctuation decidedly clear, diffuse throughout abdomen, but avoids highest parts in all positions, and always has a hydrostatic level. | Less clear; limited to cyst; not modified by change of position. No hydrostatic level. |
| Intestines float on top of fluid; hence percussion gives clear tympanitic note over the highest parts of abdominal cavity and dullness in lowest parts for all positions—*i.e.* areas of resonance and dullness change with position. | No change in areas of dullness and resonance with change of position. Dullness over cyst. Clear resonant note in all parts beyond cyst limits, *i.e.* in flanks and toward the diaphragm. |

—From Dudley's *Gynecology.*

**Expert Testimony—Hypothetical Questions.**—In an action for maltreatment of an oblique fracture of the bone of the plaintiff's right leg above the knee judgment for the plaintiff was reversed because the trial court erroneously charged the jury that they might determine the materiality of the facts detailed in a hypothetical question put to expert medical witnesses; the materiality of expert evidence being to be determined by the court, though its weight and credibility are to be decided solely by the jury.—Stanley v. Taylor, Iowa Supreme Court, 142 N. W. 81.

**Medical Practice and Good Will Not Subject to Involuntary Sale.**—A medical practitioner, after purchasing the location and good will of another physician, went into bankruptcy, one of his debts arising out of the purchase. An order in bankruptcy directed the sale by the trustee of "the medical and surgical practice and good will" of the bankrupt, as well as his leasehold interest in his office. It was held that, while whatever property interest might remain out of the bankrupt's purchase was saleable, his medical and surgical practice and good will were not. These were attributable to the personality, reputation, or skill of the bankrupt, which is entirely of a personal nature and not subject to involuntary sale, for the benefit of creditors or otherwise. Patients of the bankrupt, either present or prospective, could not be required to transfer their treatment or allegiance to another practitioner. The only force of such a sale would be to deprive the bankrupt of the exercise of his profession in the locality in which he has established or maintained a practice, a deprivation wholly unauthorized in bankruptcy proceedings.—*In re* Meyers, C. C. A., 208 Fed. 407.

### THE EXTRADITION OF INSANE PERSONS.*

BY HENRY R. STEDMAN, M.D.,

BOSTON, MASS.

IT has taken the notorious Thaw case to awaken people to the necessity of interstate rendition laws providing for the return to proper custody in their own State of insane persons who have escaped into other communities, and if his escape from Mattewan should by any possibility accomplish this desirable end it will be the only redeeming feature of a case which has, as we all know, worked much harm to the repute of the medical and legal profession and has for years greatly offended the moral sense of the country.

It certainly appears to be the psychological time for making the attempt to secure such legislation, and its success seems probable if immediate steps to that end be taken. Nevertheless, it is a discouraging fact that little has come of other similar occurrences, which for a time aroused the intensest popular indignation and loud demands for the protection of the public from this, the only such peril against which it has no legal protection. The following cases furnish additional evidence of the necessity for such legislation, and no doubt others equally striking will come to light if the need of such a safeguard be brought prominently before the public.

The savage attack upon Postmaster Morgan of New York City on November 9, 1908, in which he was shot and seriously wounded, was made, it will be remembered, by an insane man, who immediately after the act took his own life. This person was a case of dementia præcox of the paranoid type. He was sensitive and socialistic and eccentric in behavior and personal appearance. He became the butt of the boys in his neighborhood, and in 1896 asked permission of the police to carry a revolver. This having been denied him he armed himself with two, threatening to shoot his persecutors, and in 1897, when, as he claimed, they attempted to mob him, he shot one of them. In 1903 he shot in the face a fellow employee who had torn his coat in a scuffle, and refused to pay for it. He was then arrested and committed to the State Hospital at Worcester, Mass., to the present superintendent of which, Dr. Scribner, I am indebted for information regarding him. He had reflected for many years upon his adverse circumstances, gradually developing delusional ideas which involved these "toughs," whom he came to regard as responsible for his supposed reputation as a coward, etc. Failing to obtain justice at the hands of the police, he formulated a plan whereby in killing the whole gang, as well as himself, the inefficiency of those in authority would be exposed and an example set.

On May 25, 1904, he escaped from the hospital, fled to New York City, and secured employment as stenographer for a law firm. When it became known that he was there the attempt was made through the State and local police to secure his return to the hospital. The district attorney decided that he could not be extradited. In the meantime his employers, who had been notified of the dangerous nature of his insanity, maintained that he was sane and would fight any attempt to return him to the hospital. The patient at the same time retained the services of a Worcester lawyer. His dying statement was that he shot the postmaster "as the last protest of a poor man against the custom of never enforcing laws against prominent and wealthy people." He asserted that the postmaster had withheld a registered letter to him, and that he had selected the postmaster as his victim because he was the most prominent man who had antagonized him.

What better proof of the need of interstate rendition laws for the insane could be had than this case of homicidal insanity, with its history of three murderous assaults, living at large in a great city for more than four years, and so protected by the law, or rather the absence of law, that he is free to gratify his deadly insane promptings to the last? In this instance the patient had no record of crime *per se*, and on that account, in the absence of any interstate rendition law applicable to insane persons, he could not be returned to the hospital from which he escaped.

A more recent case is that of a woman of 28, a married nurse of considerable capability, intelligence, and superficial refinement, who left her husband in England and came to this country. Hers was a case of moral insanity. She was an inveterate liar, and was discharged from four or five hospitals in which she was employed in a few days or weeks. She continually defamed respectable physicians and families in which she was employed by wholly unfounded charges of gross immorality, and is reported to have administered overdoses of medicine and given morphine without orders. She had a proclivity for inventing circumstantial accounts of sexual conversations and experiences. Employers and friends questioned her mental soundness. She was arrested in the fall of 1910 for ransacking the apartments of her aged patient after her death. The robbery, which she denied having committed, was so wholesale and the articles stolen so valuable as to expose her to immediate detection. She was committed to the Reformatory for Women in March, 1911. After several examinations she revealed the fixed delusion that she was the victim of a plot to incarcerate her in order to prevent her from making

*Paper read before the Psychiatrical Society of New York, November 5, 1913, endorsed by the society, and referred to its Committee on Legislation with instruction to draft a bill to be introduced at the present session of the Legislature of the State of New York.

scandalous disclosures regarding the family af a prominent and respected lawyer, which she maintained would ruin his political career. She repeatedly declared that his withdrawal of his name as nominee for a high office was wholly on this account. She narrated fictitious visits made by him to her patient, and said that he gave a false name in order to spy upon her. She also accused the superintendent of the Women's Reformatory of general persecution of her, of intimate and coarse conversations with her of a sexual nature, and confidences regarding the management of the reformatory impossible to have occurred, etc., etc. The writer certified that she was a case of congenital moral insanity of high grade, with late development of delusions of persecution, and a menace to society at large.

She was accordingly transferred to a State hospital in Massachusetts on March 15, 1911. She escaped from that institution on September 28, 1912, and after a prolonged search by means of detectives, the police and circulars sent broadcast over this country and Canada, was finally located in a New York hotel where she had secured employment, without taking the simple precaution of assuming another name. She was apprehended and sent to the Manhattan State Hospital. Dr. Mabon, the superintendent, reports that while there the Bureau of Deportation of the New York State Hospital Commission attempted to have her returned to Massachusetts; accordingly she wrote to and secured the services of a woman lawyer, who obtained a writ of habeas corpus, on which five hearings were held. She succeeded in postponing the case and on various pretexts greatly delaying its settlement. For some time the contest was over the legality of extraditing an insane person, and only at the last moment was the evidence brought out that when transferred from the Massachusetts Reformatory to the State Hospital there she had not completed her sentence, and was still a criminal under State control. The writ was accordingly dismissed and the patient deported to the Massachusetts hospital on January 29, 1913.

Here is an escaped insane criminal of an insidiously dangerous type who has imperiled the reputation of prominent and respectable people and the peace of families, and is a liar and a thief, as well as a possible poisoner, who, for the want of any law to protect the community against such patients, nearly succeeds in gaining her liberty. It was only when a criminal charge was found against her at the last moment that extradition became possible.

Dangerous, non-criminal patients not infrequently escape from public and private institutions into other States. Many of them are poor and have no one interested in preventing their return to the hospital, and are accordingly quietly deported back when found. But when any of them have wealthy or charitably disposed but misguided relatives or friends, as in the cases cited, they are able to defy arrest and excite a great deal of misdirected public sympathy among the unthinking and ignorant. To be sure, they can be recommitted in the State to which they have escaped if their insanity be pronounced enough to awaken people to the true situation, but usually only after long and hazardous delay.

Massachusetts has the only interstate rendition law applicable to insane persons to be found on the statute books of any State, or of any country. The immediate cause of its adoption was the above mentioned assault on Postmaster Morgan. It was enacted in 1909 on the recommendation of a commission appointed by Governor Guild for the revision of codification of the laws of that State relative to the insane, consisting of Dr. Tuttle, the superintendent of the McLean Hospital at Waverley; Mr. James F. Curtis, a lawyer of prominence and recently assistant secretary of the United States Treasury, and the writer. In framing the act the commission aimed not only to secure the return to the proper authorities of patients who had escaped into Massachusetts, but also, and chiefly, to induce other States, not a few of which have copied others of her laws relating to the insane, to adopt this one as well.

The text of the act is as follows:

SECTION 87. The governor may upon demand deliver to the executive of any other state or territory any person who has escaped from an institution for the insane, public or private, to which he has been committed under the laws of such State or territory, and who may be dangerous to the safety of the public, or may upon application appoint an agent to demand of the executive authority of any other State or territory any such person who has escaped from such an institution in this commonwealth. Such demand or application shall be accompanied by an attested copy of the commitment and sworn evidence of the superintendent or keeper of the institution stating that the person demanded has escaped from such institution, and by such further evidence as the governor may require.

SECTION 88. If the governor is satisfied that the demand conforms to law and ought to be complied with, he shall issue his warrant under the seal of the commonwealth to an officer authorized to serve warrants in criminal cases, directing him at the expense of the agent who makes the demand, at a time designated in the warrant, to take and transport such person to the boundary line of this commonwealth and there deliver him to such agent. The officer may require aid as in criminal cases.

SECTION 89. A person who is arrested upon such a warrant shall not be delivered to the agent of a State or territory until he has been notified of the demand for his surrender and has had an opportunity to apply for a writ of habeas corpus, if he claims such right of the officer who makes the arrest. If the said writ is applied for, notice thereof and of the time and place of hearing shall be given to the attorney-general or district attorney for the district in which the arrest is made. An officer who delivers such person in his custody upon such warrant to such agent for extradition without having complied with the provisions of this section shall forfeit not more than one thousand dollars. Pending the determination of the court upon an application for the said writ the person shall be detained in custody in a suitable hospital for the insane.

SECTION 90. If the application for the arrest of a patient escaped from an institution, public or private, in this commonwealth, is complied with and an agent is appointed, his account shall be paid by the institution from which the patient escaped, but the governor may direct the whole or part of such account to be paid by the commonwealth.*

Our commission felt strongly and was sustained in its belief by the best legal opinion, that the courts would use every endeavor to sustain such obviously beneficent legislation. The only clause of the Federal or State constitution that might be infringed would be the provision to the effect that no person shall be deprived of his liberty or property without due process of law, but we were strongly of the opinion that the detention of a person on the request of a Governor of another State with evidence that such person had escaped from a hospital to which he had been lawfully committed would well be considered as a detention under due process of law and consequently that the statute would be upheld.

*Commonwealth of Massachusetts vs. Klaus. Decision rendered July 7, 1911. In 145 Appellate Division Reports of Supreme Court of New York, page 798.

In this connection a decision recently cited by the legal member of the commission is significant. In that case* a statute which required the attendance of a witness in a court of another State was held constitutional on the broad ground that the power of a sovereign State to direct and control the actions of persons within its borders was without any limitations except those expressed in the constitution, and that there was no provision of the constitution which that statute seemed to infringe. While the basis for this legislation was the administration of public justice it has nevertheless a bearing on the interstate rendition of insane persons to this extent at least, that it shows that a State may cause a person who is not a fugitive from justice and who has committed no crime to betake himself outside the borders of the State at the request of officials of a sister State.

It has been thought that the amendment to the New York statute advocated by the Bar Association of that State, whereby the verdict of "guilty but insane" shall be substituted for "acquitted by reason of insanity" would, if it became a law, accomplish the same purpose by establishing the patient's status as a criminal subject to the usual methods of dealing with crime, among which is extradition. This is true as concerns a limited number of cases, of which Thaw's is an example, which come to trial. But such a provision would not affect the return of a larger proportion of dangerous patients whose insanity is so unmistakable that they are immediately committed to hospitals for the insane without trial.

New York City, with its immense and cosmopolitan population, its many insane and its countless opportunities of all kinds, whether for work or pleasure, for crime or its concealment, is more likely than any other city not only to furnish by far the larger number of escaped insane patients, but to be looked upon as a safe refuge by those from other States, and the cases before us are evidence of this fact. Is she not in duty bound to make every effort to protect herself and her sister States by some such legislation? Should New York follow Massachusetts in adopting an interstate rendition law, her example would have great influence in shaping the policy of other States in the same direction.

## A FURTHER STUDY UPON MENTAL TORTICOLLIS AS A PSYCHONEUROSIS.†

By L. PIERCE CLARK, M.D.,

NEW YORK.

In a previous paper** I undertook to show that certain types of tic such as mental torticollis were but continuations of habit movements. The tics remain as fragments of the complete habit and persist as crude symbols which serve as a most intimate and deep need of the abnormal personality of the individual patient. By the analysis of an illustrative case in that paper the habit movement was traced back to earliest infantile life and found there to have been closely interwoven with the mother complex initiated by a caressing, petting act of affection by the mother. It was also shown that the mother's part of the neurosis but served to waken and fasten upon the child an autopleasurable act, which act or habit movement took on secondary autoerogenous satisfaction in later life. The act, continued and modified in later life, constituted the tic from which the patient finally sought relief. It further developed that the main reason for the habit movement and its tic successor being irrevocably attached to the patient was due to the inherent sense of inadequacy of feeling and will generated from the conflict of doubt, the latter conditioned upon the most primal antagonism of the hate instinct in its process of sublimation by the love instinct. The whole chain of events served to form the vascillating, indecisive character and will of the obsessive neurotic of which the torticollic is but one of the group characters in the incompletely evolved neurotics.

Since the first study was made, another and somewhat similar type of mental torticollis has been under analysis and treatment. The case about to be detailed might be termed acute mental torticollis. However this may be, the tic movement is in no sense differentiated from the ordinary mental torticollis, only when we came to study the case from its genesis does it appear in the light of a psychoneurosis. In presenting the case history in which a psychosynthesis is shown I know of no greater test of scientific faith on the part of the hearer than that called forth in accepting the issues and interpretation of such a presentation. This tax would not be so great if we were permitted to develop the life history of the case under his own eyes, like a Chinese drama, but the exigencies of time for presentation of scientific data in any such study is very limited; therefore such reports must necessarily be fragmentary, mere vignettes of certain scenes in the individual life being shown, or time is only permissible to show specific reactions or trends that lead to the development of the frank neurosis. Such presentations have not only been charged as being dishonest, unscientific in arrangement of fact, but many believe that they lead one into bad intellectual habits of sizing up only the data that fit the final setting in diagnosis, or that they make the mosaic pattern of the clinical picture seem unnatural and not as it would appear to an independent observer. However this may be, we really have no redress at present, but must be content to report cases in as concise and graphic a manner possible, trusting in this way to persuade the incredulous hearer of the intellectual honesty and fairness of the reporter. If we shall but convince a few investigators in the study of the psychoneuroses that we all need to go still deeper into the intimate character and makeup of the psychoneurotic individual, we shall have labored to good purpose. The future must decide what the final fruition will be.

The case of mental torticollis which I shall present is as follows:

*One of the highest legal authorities, a former attorney-general of Massachusetts, pronounces this act as constitutional and manifestly in the public interest because if uniformly adopted a State could enforce its responsible and continued control over a dangerous insane person escaping into another State and the community into which he had come would be delivered of the danger of his presence and responsibility for his care. The operation of the act, however, might be hampered because of constitutional questions arising in habeas corpus proceedings regarding the expulsion from a State of any person other than a fugitive charged with crime. It is therefore, he thinks, of the utmost importance that such statutes should be most carefully drawn in order to eliminate these questions so far as possible.

†Read before Section of Neurol. and Psychiatry, N. Y. Acad. of Medicine, Jan. 13, 1914.

**Some Observations upon the Etiology of Mental Torticollis, N. Y. Neurological Society, December 2, 1913; MEDICAL RECORD, Feb. 7, 1914.

Miss F. B. C. was referred to me by Dr. C. A. McGuire for analysis and treatment. She suffered from a most persistent right spasmodic torticollis with an added spasm in the left trapezius and splenius, a not uncommon combined tic. The condition had existed for eleven months and had defied all the ordinary plans of treatment. Indeed, the tic had grown worse of late in that it was less easily controlled and all the muscles in the tic movement enlarged. They were in more or less clonic and tonic spasm during the waking state, and all the muscles concerned in the act were sore to the touch and ached. The patient in the extreme position of her tic is so typical of mental tic that it leaves nothing to be desired from a classic point of view. Suffice it to say that the condition present was the one usually encountered in such cases without anatomic or neurologic evidence of gross disease aside from the muscle hypertrophy which was directly produced by the tic movement itself.

It will be understood that the case history is much abbreviated and is given in the usual though reversed order in which the facts were obtained, that is, it is presented as a psychosynthetic study instead of a psychoanalytic one. Anyone acquainted with psychoanalytic methods fully recognizes the advantage of this manner of presenting it in the inverted order of its historical acquirement.

The patient is 29 years old and is the second in a family of five children, four of whom are living. Our patient is unmarried and now lives at home alone with her mother. The two brothers are regular and ordained priests, and her younger sister is a nun in a convent. The patient had a normal birth and childhood as ordinarily understood, aside from an attack of acute chorea preceding an attack of inflammatory rheumatism at five years of age. The St. Vitus' dance recurred again at eleven or twelve for a few months. She had a high school and business-college education and has been a stenographer and private secretary in an insurance firm for nineteen years. She left business December, 1912, from what she termed a nervous breakdown from overwork.

In opening the infantile life we find that our patient was an affectionate, sensitive child, but in the face of little affection from the parents, at four or five years of age she became a shy, diffident, reserved, and timid girl. Her mind developed equally. She was not boisterous as a child, and always acted older than her years. She was not nervous in her manner but felt an inner tension. She was not free in her associations with other girls or boys, and was very self depreciatory; but in spite of it was able to stand on her own feet. She depended upon the opinions of others largely, and strongly desired their approbation. She often felt and made attempts at self justification although her egotism was repressed. She was not conceited but quite vain and self conscious. Although she was inclined to a great deal of self pity she could stand real pain pretty well. At the age of eight or ten she felt a great desire for social life, but was not successful in forming friendships with the exception of a few girls as she could not get *en rapport* with a large group. As a child she had a great horror of death and was obsessed with the thought that the world was to burn up, and often prayed she might die before it burned. Every fire in the neighborhood made her think that the end was near, and consequently she was in frequent childish panics that she was about to die. She thought she had heart disease and would die of it. Through a lack of parental understanding the patient was not able to talk over her fears with them, and she dwelt upon her ills when alone. She grew up reserved on all topics and was frequently blocked by various scruples in situations requiring free activity of physical or mental acts. She usually lets other people do the apologizing when misunderstandings occur, and takes no initiation in making amends, and is quite apt to think she is right in most life issues.

From eight to twelve patient had frequent attacks of fear of death, especially at night, when she would rush to her father for protection and to calm her fears. She felt her father "was strong and masculine" and could ward off this death panic where her mother would fail.

At seventeen she felt her life at home was too monotonous and unsatisfying, and left it for a business training in New York. She easily qualified for a stenographer and obtained and filled a very acceptable position of secretorial work in an insurance office, as before stated.

Patient follows the father type in temperamental makeup and one of her brothers is also of the same type, between whom and the patient there is the best of understanding. Patient did not enter the society of the opposite sex until seventeen. She paid more attention to older boys then and preferred married men. Her love affairs with men were always casual and broken off on trivial grounds. She always grew tired of them. In friendships she demands a great deal of loyalty. She has not been especially attached to friends, with the exception of two girls. The first girl friend, whom she knew when she was eighteen, was a very close and intimate one. She formed a close attachment and took her as a model and ideal. She always felt rather awkward with her, and shy and diffident. Everything that the patient did, however, was much praised, and she was made to feel that all things were quite all right. The patient took to quoting her, walked, talked, and dressed like her. This friend got married rather suddenly without letting the patient know, which made her rather jealous, and she was very unhappy for a year or more, until the second girl friend appeared, of whom she was very fond and submissive; yet this friend reprimanded and corrected her in many ways, much to her chagrin, but she nevertheless loved and obeyed her. She was very religious in contradistinction to the other friend, who was quite the reverse. Each of these attachments lasted for two years, one following the other, dating from eighteen to twenty-two.

Her employer, the manager in the office, was an elderly man, very kind and considerate, and there gradually grew up between them the feeling of father and child. Her feelings were about equally divided between the "business father" and her own father. They both died six months apart about two years ago. Her father died of apoplexy six months after the elderly employer. His death agony was in the patient's arms. The father died in convulsions, there was congestion in face and stertorous breathing which frightened the daughter so much that she did not sleep for two nights, and she thought she would die the same way if she went to sleep. She accused herself of hastening his death by bolstering him in bed. She did not give way to her feelings, but collapsed two days after his death. First she felt a dead weight in the lumbar region, which quickly passed up to the shoulders and neck; they grew rigid, numb and cold,

the head felt as though it would burst, while the heart seemed as though it were about to stop and she were on the point of losing consciousness, and she knew she would die (apoplexy phantasie). Though she suffered greatly from all these symptoms, she had a quiet satisfaction that it was "all for the best."

One should particularly note the patient's exact description of the father's death agony, as it makes her own apoplexy phantasie the clearer: "The head was drawn back and turned to the right, the brows were corrugated, the arms were rigid and cold and drawn up near the neck as though holding the head in that position; the face was livid as though the heart and breathing had stopped, and the whole body trembled."

Many times as a child patient thought that the father didn't have very much in life, and since being near New York seemed to illy adapt himself to conditions and surroundings, and that she ought to make up to him for these deficiencies. Her mother always seemed like a sister to her. Patient was the oldest girl and took the household duties upon herself. After she left home at seventeen affairs about the home were carried out according to patient's directions. She seemed always to have made the decisions in regard to any new moves about the home. Occasionally the mother took her to task for going out to see some friends, inasmuch as the girls she visited had brothers; the mother told her she should be aware that she, the mother, was older than the patient, and knew that she ought not to visit these young men under the pretext of visiting their sisters. This caused anger and disappointment. At the time of the father's death, the mother made the patient very nervous as she seemed to take the matter so much more calmly than the patient did. The mother saw people who came to inquire about the death, and did many things which the patient said she herself ought to have done. She felt as though the mother was rather unfeeling and not aware that she, the patient, felt as if she were dying; the mother didn't seem to be at all concerned in regard to our patient's health, which made her nervous and antagonistic toward her. In this way she indicates the unconscious rivalry which she had against the mother, and of the feeling of replacement in her attitude to the father that made his death so serious to her, and also produced the apoplexy phantasie which was the basis for the desire for spiritual reunion. The feeling toward the mother gradually faded away; she believes, however, that the mother never really understood her feelings because even as a child she thought that her parents, being at considerable strife, didn't exhibit much tenderness toward each other, and that neither was much suited to the other. The father was not as attentive as he ought to have been, although the whole situation was quite reversed during the last ten years preceding his death, during which time she felt that her mother ought to have known her father better and not have antagonized him so much. She didn't feel able to show although she felt proper affection toward her father in late years. A girl friend who frequently visited her was very affectionate and demonstrative toward her father, which made the patient jealous and made her also feel more like a stranger in her own home.

Our patient's dreams immediately after the father's death are significant. The father appeared to her sad and sitting out in the cold misty night. He was illy clad in white and was shivering. She tried to persuade him to enter the house but he would not. She attempted to carry him in and on raising his head she saw that he was dead. She wakened in a nightmare just as she had determined to stay there with him. She found on waking that her arms were numb and rigid and her head felt as though it would burst. In the second dream the father appeared happy, talkative and much more affectionate than during life. In the midst of the pleasure of seeing him he announced that he was dead and must go away. Our patient strove to follow him, and awoke in a nightmare again with the apoplexy phantasie as in the first dream.

The patient did not cry at her father's death nor at his funeral. She stayed around home for a few days, having chills and tremblings at night, and was then sent to Atlantic City. Several times while there she had trembling fits and numbness in the arms as though the circulation had stopped. Then fright and anxiety succeeded and she became wakeful. When this clinical setting gradually disappeared there occurred pressure in the frontal region of the head. A more or less persistent headache succeeded this. She felt as though the head would burst and that the veins inside were struggling to break. This latter symptom gradually ceased in about six weeks and she returned to her office work. For a little more than a year prior to the death of the father and the aged employer a young man took charge of the work. She felt some stress in readjusting herself to the work, as the new employer was overexacting, but nevertheless more interesting. She now began to worry about pleasing him and did extra work as the business enlarged. Inasmuch as she was old to the business and he was new in the department he seemed to expect more of her from day to day. She was much flattered that he depended so much upon her ability. Although she worked harder, contact with the new employer steadily enlarged her scope of vision on life and its affairs; it softened her and made her ambitious to progress. She often dreamed of him in an intimate manner and her waking thoughts were much concerned with the new work, and she shared his desire to enlarge the business. In short, she fell in love with him, which was a one-sided affair as the employer was married. There was no declaration of affection on either side. She thinks she rather liked him the more because he was married, as she could allow herself more range in fancy because the matter could go no further. After a few months of repression of her feelings she found herself day-dreaming for a more intimate friendship, and the old headache came back once more and was made worse as she sought to apply herself more intently to her work. Some more office force was employed and she came less and less in contact with him, but felt the need of his presence the more. Her mental abstraction soon became apparent, and her employer gave her the name of "Miss Make Mistakes" in friendly badinage. The old tightness and numbness in the shoulders, arms, and neck returned and she steadily failed to compensate or get square with it by more intent application to her work. She now had severe headache, heavy feelings in the legs, tightness and numbness in the arms passing up into the neck muscles.

A new situation was now introduced. Her desk was located so that the manager's was to the right of her. Strangers also entered the office in that direction, and in order to protect him from un-

necessary interruption she kept a keen lookout to ward off various people. Then, too, whenever she looked up he always seemed to be looking at her; he frequently stood at the right of her desk to give her dictation. He was six feet three in height. It is but necessary to say in explanation for intruding the physical stature of the employer here that the patient's tic is to the right, the head being tilted upward at the same time, a species of human heliotropism is shown in our patient. In the patient's own words, "he was the center and life of the business and greatly looked up to by all of us." Before the tic broke out, however, the neck became stiffer, the head more congested, and to ease the latter—to shut out distraction and noise, and to keep the head and mind steady she sat many hours at her work with both hands, especially the right, pressed to the temples; after a time this protective mechanism of obsessive acts became insufficient and the head wobbled and shook in spite of everything, gradually turning to the right. The will broke and the complete and uncontrolled tic came through. She then left her work at the office for treatment of nervous prostration. However, as soon as the head was allowed to turn in full excursion to the right and upward, the tension in the head, arms and shoulders all disappeared and she felt better.

We have here, then, a case of acute mental torticollis in an unmarried women of thirty-nine, whose tic is a form of neurosis occurring in an individual who was very sensitive as a child, who had panics and fears in early life, and who had a strong father-attachment. The latter prevented her coming into free contact with life in any of its larger feelings and returns of affection and friendship. On the death of the two fathers she developed an apoplexy phantasie to gain a spiritual reunion with the father; the libido then gradually returned to actual life and she became attached very strongly to an unfortunate and one-sided love affair. The compensation or sublimation of it was insufficient or failed, and the tic as we see it became the fragment symbol of the life wreckage and unfulfilled desire. It may be that some critics would place the case as a neurosis to be classed with the obsessions, in view of the fact that the hands are still employed as a specie of exorcism of the tic movement, that there was a certain inability of the love instinct for free play. There seems to have been little doubt connected therewith but rather a too firm father attachment hindering its free range. The situation would seem to me, however, to be a breaking through of a sexual repression and therefore a sexual neurosis of the old hysteric type. Although I have seen the case but comparatively few times, not more than eight or ten, I may say she has shown great improvement. "She feels freer mentally, more able to do various kinds of work, sleeps well, without nightmares, and is less centered on herself. She comprehends the line of treatment and looks frankly at the defects of her inner life and no longer takes satisfaction in having a misunderstood disease." The extra muscle tension outside the field of tic movement has disappeared. There is no more pain and tenderness in the tic-producing muscles, the head remains quiet without effort for fifteen minutes at a time, and the general physical health is much improved. The process of disintegration of the tic movement on its way to betterment is interesting and significant. First the entensity of tonic spasm diminished to a clonic one; the head was turned less to the right and, at the end of the excursive movement to the right, the chin is no longer tilted up; yet the eyebrows are occasionally contracted. In other words, there is less helioptropism as it were, inasmuch as the sun attraction has been withdrawn.

In conclusion it is interesting to note that the patient's belief that the father's death is the real cause of the tic is probably quite true; the modern love affair probably would not have resulted in this particular kind of tic if the defense armor in motor control had not been weakest at this point. Finally, it would seem more than mere chance that this whole family of four brothers and sisters have missed the main pathway of normal expression of sexuality. The younger sister is a nun, the two brothers are priests, and the fourth, our patient, has had the mischances we have herein detailed.

The points of similarity in the two cases of tic I have presented are the mother and father love fixation respectively. It is also shown in a sense of shyness, timidity, a lack of push in the love expression to make a broad sympathetic and friendly contact with the outside world; a certain lack of ability to properly gauge and direct the love instinct is present in both individuals. The difficulties at bottom in hysteria and the obsessive neuroses do not seem so very dissimilar, but in our tic individuals the very precocious sexuality allies them nearer to the obsessive types than to hysteria. The aggressiveness of the sex hunger so easily stirred in our first patient by the mother's petting and caressing, was shown at four or five years of age in the latter female patient in an extra regression, as one might expect, into mental infantilism of fears, timidity, frank panics of death and free floating fear of world destruction. The doubt of being both physically and spiritually saved, if given in full in the latter history of this case, would have convinced any one that we were dealing with a doubt neurosis in its earliest development. Through it all was shown the unsuccessful psychosexual repression. However, one must not think the tics can be easily classified with the doubt or obsessive neurosis without a struggle, inasmuch as many ticeurs on close examination show that their tic often appears as the physical *conversion* of a painful affect or idea, thus lending much color to the contention that the tic is a physically converted affect, a hysteric complex, rather than a *substituted* obsessive idea neurosis. It may be found desirable one day to class the tics as a new type of transition neuroses between the hysteric and obsessive neuroses. Certainly many cases of tic have symptomatic settings from both clinical pictures. It is interesting to note, however, that the fearful and tragic setting of the second patient's affect into an apoplexy phantasie, being as the friends and patient thought solely conditioned upon a feeling of remorse and neglected attentions to the father, really belonged, as shown by its very intensity, to another and larger unconscious content, the long repressed love for the father. This is one of the firmest attachments of the second case to the obsessive type of neurosis. It is, of course, well known that the two affections have much in common in causation and symptoms and frequently appear in combination. I should say that case one is more of the obsessive type, while case two is nearer the hysteric one.

It becomes much more understandable now why most textbooks on tics are shot through and through

with the idea that the real genesis of the tic is a painful or unpleasant physical experience, and that they meet no real conscious need, when we see that the tic is often symbolically nonsexual. The tic then goes on devoid of motive and is senseless. In this respect it is no worse, however, than the often ambiguous wording of dreams. The obvious task hereafter will be for us to find what real satisfaction lies back of the tic forces that strives to give it physical meaning, just as the dreamer strives to give the real psyche a motif in the dream imagery. One should also be aware that the very physical treatments in the tics, though given for secondary defense against the obsessive tic movements, the patient may easily convert them into obsessive acts themselves. Thus the penitential measures of military exercises in calisthenics, the irksome ceremonials of mirror training, the observation of numbers in counting exercises may all be ultimately bound into the obsessive acts and thoughts and become a part of them. Even the surgeon must join with us in our teratological sins in applying corrective splints for the ticeur's infirmity and on which the patient builds mollusc fashion new formulas or obsessive acts.

The question naturally arises here, what about old systems of treatment of mental torticollis and is psychoanalysis alone sufficient to cure? My short experience in handling these cases is too limited to formulate any hard and fast rules of treatment. There is little doubt in my mind, however, that a lifelong maladaption of the psyche and the defects of inner adaption to the outside world require years for reconstruction. While the disease phenomenon may be greatly curtailed, be made to practically disappear by psychoanalysis, the tic neurosis—based as it probably is in most cases upon the warring contentions of the hate and love instincts, the most primitive mental infantilism—is almost beyond full correction; the very foundations of mind are at issue and it is just this fact that makes the tic and obsessive neurosis the most malignant psychoneurosis. Then, too, one has little positive knowledge of the correlation of structure and function of brain and mind. The manner and power of transmutation of thought into physical acts and *vice versa* are beyond even profitable speculation at this time. One can easily understand how a tic habit may continue as a detached pathologic function even after it has been deprived of its potential significance. It may not be unlike a guide-post which still points the way along which great traffic once took place although the road has long been abandoned to travel and its terminus may no longer even exist. In such instances the physical, moral and spiritual training, in their best sense, find a fitting and constructive upbuilding of personality and character. One should be very sure, however, that the psychic ground is very thoroughly cleared before assisting at such a delicate task as trying to set up soul ideals for another, though metaphysicians and the clergy in no wise fear to rush in where even physicians permit themselves to rarely enter.

84 East Fifty-sixth Street.

**Oxygen to Remove Carbon.**—Peroxide of hydrogen squirted into the intake manifold through a small hole near where it forks, and while the engine is running, will be carried into the cylinders and the excess of oxygen will quickly burn out the carbon deposits.—*Motor.*

## THE EVOLUTION OF THE STUDY OF ANATOMY AND ITS IMPORTANT RELATION TO THE DEVELOPMENT OF SURGICAL KNOWLEDGE.

By J. EWING MEARS, M.D., LL.D.,
PHILADELPHIA.

In a paper presented to the American Surgical Association the writer gave a brief and concise account of the history of anatomy, beginning with its study among the Greeks in the time of Hippocrates—the father of medicine—(460-357) to the latter part of the eighteenth and the beginning of the nineteenth centuries, when great perfection in its study was attained. Two great epochs mark the unfolding of the science of anatomy, and give character to its development and growth. These are (1) the dissection of the human body and (2) the introduction of the microscope as an aid in the revelation of the minute structure of the tissues and organs of the body. Omitting in detail the history of the science the writer is moved to place on record his experience, as a student and teacher of anatomy for many years during the last half of the last century, in certain matters relating to the methods of study and teaching of that period of time.

As has been stated, the great advance made in the study of the science of anatomy began with the dissection of the human body. The manner in which bodies have been obtained for this purpose furnishes an interesting chapter in recording the progress which has been made.

In the earlier days the bodies of condemned criminals were given for the purpose of dissection. Until authorized by law the bodies used in dissection were obtained largely by stealth from places of sepulchre. Those who practised dissection were socially ostracized, and legal enactments were directed against them. Later the commanding position of those who devoted themselves to the pursuit of anatomy gradually removed the prejudices, and laws were enacted giving the bodies of prisoners and paupers to investigators for the purpose of anatomical study.

"Frederick II, Emperor of Germany (1215-1250), is said to have forbidden any one to practise surgery without a competent knowledge of anatomy, and to have provided that every five years there should be held at Salerno a public dissection to which physicians from all parts of the Empire were invited. The senate of Venice decreed in 1308 that a human body should be dissected annually. Philip II of Spain interrogated the faculty of the University of Salamanca, then the leading theological school in Europe, as to whether dissection was permissible. After due deliberation, a reply was given that since knowledge of anatomy is useful to man dissection may be allowed."

In Great Britain, in 1827, in the universities and medical schools, dissection was made compulsory and the demand for bodies became so great that it was impossible to supply it. This condition led to the organization of a body of men known as "resurrectionists," with branches in every large city, which supplied the needs of the institutions by systematically robbing graves. Among these were two men in Edinburgh, Burke and Hare, who resorted to the murder of poor and friendless persons, whom they enticed into their dens, killing them by suffocation and selling their bodies to the medical schools

for dissection. This method of procedure gave rise to the term "burking," which has to-day a place in the dictionaries, and describes the condition. Two men, Bishop and Williams, practised the same method in London. This crime was stopped in Great Britain in 1832 by the enactment of an anatomy act, which legalized dissection and under restrictions gave available material to medical schools and to those authorized to use dead human bodies for dissection. In 1783, in the State of New York, a law was enacted making it legal to dissect the bodies of executed criminals.

It is suspected that until recent years, when in our own country anatomical laws have been enacted and enforced in several of the States, these methods were employed to obtain bodies which were sold to medical institutions. Grave-robbing was the usual method of obtaining bodies, not only by those who made a business of it, receiving in most instances large sums of money in order to compensate the parties engaged in the business for the great risks taken and the hazardous nature of their occupation, but also in small communities by students and even professors, whose needs for anatomical material compelled them to resort to such methods.

These excursions have been in several instances attended with the receipt of gunshot wounds by those engaged in the enterprise, inflicted by officers of the law having the duty to protect cemeteries from such illegal invasions, or by friends who were doing guard duty. It has happened also that through ignorance the bodies of persons of position and influence in communities have been resurrected and have been found by relatives and friends (whose feelings were greatly outraged by this violation of the sacredness of sepulchre) in the dissecting rooms of colleges.

A notable instance of this character occurred in one of the medical colleges of the West, where the body of the father of a most distinguished citizen, occupying a high place in the councils of the Nation, was found suspended by the neck in the "lift" of the anatomical room of the college.

The enactment soon after of an anatomical law in that State stopped the business of the resurrectionist and gave inviolate protection to the graves of all.

When the writer, quite a half century ago, began the teaching of anatomy it was very difficult to obtain anatomical material, and the cost, owing to the methods which were employed, was very great. On one occasion a resurrectionist was detected in his unlawful acts, was arrested, tried in court, convicted, and sentenced to a term of imprisonment. A professor of anatomy in a medical college, who was regarded as an accessory after the fact, was charged with conspiracy in the acts of the grave-robber, was arrested, tried, and acquitted, escaping conviction by a narrow margin. Practically he had nothing to do with the acts of the grave-robber; he simply paid for bodies deposited in the college building, with the source of which he did not concern himself. Technically, possibly, he was *particeps criminis* in the sense of being a "quasi receiver of stolen goods."

The case aroused great interest in the subject of obtaining dead human bodies by law for the promotion of medical science, and the teachers of anatomy under the guidance of Dr. W. W. Keen and the writer took active measures to secure the passage of a law of this character in the State of Pennsylvania. With great care and under legal advice an act was drafted and presented by a committee, of which the writer was a member, to the State Legislature, then in session, accompanied by a petition praying for its enactment.

The provisions of the law created a board, consisting of the teachers of anatomy and surgery in the medical schools and colleges of the commonwealth, which board after organization was to have entire control and charge of the receipt and distribution of all dead human bodies which the terms of the law gave to it. Each teacher of anatomy was required to give to the Prothonotary of the Court of Common Pleas, in the county in which he resided, a bond in the penal sum of one thousand dollars, that he would obey the provisions of the law. Traffic in dead human bodies was punishable by fine and imprisonment.

The officers of all municipal, county, and State institutions, having charge of the dead bodies of those unclaimed by blood or marriage relatives, to be buried at the public expense, were required to deliver such bodies to the board created under the law, all expenses to be borne by the board. The details of the conduct of the business of the board as to the distribution of the bodies coming into its charge to the institutions, schools, and those entitled to receive them was provided for by the rules adopted by the board. Exemptions were made in cases of old soldiers and certain others.

This law displaced one on the statute books of the State which was very defective, and was in all respects correctly drawn so as to protect the community and to promote medical science by giving in well-ordered manner dead human bodies for anatomical and surgical purposes. An essential feature of the law was the prevention of the traffic in dead human bodies which had existed before and which had wrought such shameful acts of spoliation of the resting places of the dead. The law of 1867, displaced by the act of 1883, was limited in its execution to two counties of the State, and gave the bodies of those who had no friends whose feelings could be wounded by their dissection. In 1855 a law had been enacted for the protection of burial grounds. A rigid and exacting rule of the board, requiring that a certificate of death made and signed by a reputable practitioner of medicine should accompany each dead body, made it impossible for any bodies to be delivered to the board unless under proper authority.

Feeling the great importance of the introduction of the provisions of this law in a proper manner, the writer accepted the position of executive officer of the board created by it, and for several years was interested in its execution, in order that all who were entitled under the law and who had complied with its terms should receive an equitable distribution of anatomical material and at a cost which encouraged the liberal use of material for anatomical and surgical purposes.

He was interested, as one of the features which attended the supply of dead bodies, in some of the acts practised by relatives who offered the dead bodies of members of their families to the anatomical board in order to escape the cost of interment. In all instances a certificate of death by a known reputable physician was required and the full consent of all parties related by blood or marriage was demanded to be placed on file in the records of the board.

One instance was so unique in its character that a brief account may be interesting in this chronicle..

A man of middle age, well-dressed as to hat, gloves, and top-coat, presented himself at the office of the board on one occasion and inquired whether the Anatomical Board purchased dead human bodies. On being informed that one of the purposes of the enactment of the anatomical law was to prevent traffic in dead human bodies, he stated he was ignorant of the law, and explained his reasons for making the inquiry to be a desire on the part of certain members of his family to obtain wearing apparel with the money received by the sale of the corpse. He was informed of the terms under which the board would receive the body, to which he agreed. He then stated that the body which was to be delivered to the board was that of his wife, who had not yet died, but who was ill and whose death was expected in a short time. With this statement he departed, and in three weeks returned with the information that death had occurred and requested that the undertaker in the service of the board would arrange a "little funeral" at his house. The services were held in the home of such character as belonged to well-to-do people, and the body came into the possession of the board without any expense to the mourning family. One year later this husband of frugal mind died, and his daughters, who desired to be adorned, as stated by him, their father, with wearing apparel purchased with money derived from the sale of their mother's dead body, arranged for the cremation of his body at the crematory where they had been informed by him the body of their mother had been cremated and her ashes sacredly in-urned. By tactful management the officers of the crematory accounted to the deceived daughters for the absence of the urn containing the ashes of their mother, and, through the records of the municipal Board of Health, traced the body to the Anatomical Board, which had in due order distributed it to the anatomical department of one of the medical institutions for dissection. The probate of the will of this devoted husband revealed an estate of $30,000. No suspicion of foul play was entertained in this case, the death certificate, signed by a well-known physician of the community, stated the cause of death to be "tuberculosis."

Members of the medical profession have at times, by last will and testament, given their bodies to medical institutions for the promotion of medical science by dissection, the skeletons of which, with certain organs were to be deposited in the museum of the institution. An act of this character on the part of one of the most eminent medical teachers of the country contributed his skeleton to a museum, which has become in process of time, by many valuable additions, a most important department of instruction in a great medical school.

In one of our cities, which for many years has been a center of medical teaching and medical authorship, a number of prominent members of the medical profession, teachers, and authors some years ago entered into a pact to give by provision of their wills to a museum connected with the medical department of a university their breains for dissection and study. Already a number of brains have been deposited in this collection and valuable information has been accumulated.

The preservation of dead human bodies for the purposes of dissection has been an important part of anatomical investigation. In order that a complete dissection, with proper study, should be made it was necessary that the body should be preserved in a condition as nearly natural as possible for an indefinite period. Not only should putrefaction be prevented, but the tissues and organs should be so treated as to retain the natural color—that present during life—and also a condition of flexibility through which the normal positions of organs and relations of parts were maintained.

The earliest accounts recorded with regard to body preservation after death are found among the ancient Egyptians, who carried the art of embalming to a high degree of perfection. Two reasons were assigned for this practice: (1) The scarcity of wood which prevented cremation, and (2) the impossibility of maintaining permanent interment in the ground owing to the recurring inundations of the Nile, and consequently the occurrence of serious unsanitary conditions by disinterment of bodies in states of putrefaction. Religious beliefs with regard to the resurrection of the body and a future life, it is stated, have also inspired certain peoples to preserve the embalmed bodies of their dead with solicitude. The process of embalming consisted in evisceration with as little mutilation as possible, the brain being removed through the nostrils by a bent iron implement, and with the injection of drugs. Various medicaments, notably aromatics, were injected into the cavities and the body immersed for a varying period of time in a solution of natron.

The early anatomists, as well as those in modern times, employed various methods of embalming. William Hunter used essential oils, alcohol, cinnabar, camphor, saltpeter, and pitch or resin. Tar, salt, asphalt, Peruvian bark, camphor, cinnamon and other aromatics and corrosive sublimate have been used; also the chloride and sulphate of zinc, the acetate and sulphate of aluminum, creosote and carbolic acid.

Before the occurrence of the Civil War, and some time after, the methods of preservation of bodies for dissection were crude and defective. A strong solution of the chloride of zinc was injected into the arteries, using either the aorta or femoral arteries for the purpose, and the bodies, doubled up, were placed in large casks containing alcohol, the price of alcohol at this time making it a fairly economical procedure. When wanted for dissection the bodies were removed from the casks in a state of rigidity which required soaking in a tank of water for several days before it was possible to restore them to normal shape. Then a solution of plaster-of-paris was injected into the arteries to facilitate their recognition in dissection.

When the cost of alcohol, by reason of post-bellum taxes, became prohibitive, bodies, after the chloride of zinc injections had been made, were kept in tanks containing a saturated salt solution. Bodies injected with the chloride of zinc solution as a preservative were very defective for dissection purposes by reason of the bleaching of the tissues which resulted and the tendency of the parts to undergo dessication. In order to overcome these conditions several other agents, notably the bichloride of mercury and carbolic acid, were tried, but these failed to preserve the tissues and organs of the bodies in a fit condition for a sufficient length of time to permit complete dissection. The perfection of cadaver preservation for anatomical purposes came with the use of cold-storage vaults, in which the subjects were placed and kept in a temperature sufficiently low to prevent putrefactive changes—40° to 50° Fahrenheit.

To the agents above enumerated, carbolic acid, creosote, alcohol, saltpeter, glycerine, arsenate of soda, and formaldehyde may be added in solution and thrown into the arteries by gravity. The color of the tissues is not changed by these agents, and the cadaver when taken from the refrigerator and thawed is in excellent condition for dissection. Instead of plaster-of-paris, melted wax or a solution of starch colored with vermillion may be used to fill the arteries and arterioles to assist in their dissection.

The methods employed in disposal of the remains left after dissection of bodies have varied. Originally they were thrown into a pit and a solution of lime poured in so as to promote destruction. In one institution the most reverent care is taken of the bodies and of the remains. The bodies are brought to the institution in coffins, in which all portions of the dissected remains are placed and every care to preserve the identity of each body taken. The institution, in a burial ground owned by it, inters the remains and marks the grave by a suitable headstone. The modern method accomplishes the destruction of the remains by incineration in a suitable furnace.

The methods of teaching anatomy to students have undergone changes which have been in harmony with the development and growth of the science. Since the time when Vesalius "proclaimed openly that the structure of man should be learned by the inspection of the human body, true knowledge could alone be obtained by the study of this, the only correct authority the body of man itself," and Harvey stated that he "taught anatomy not from books but from dissections, not from the suppositions of philosophers but from the fabric of nature," instruction in anatomy has been conducted by teachers by lectures illustrated by demonstrations on the dissected cadaver before the entire class of students, with practical instruction in the anatomical room; the students in sections being required to dissect, under supervision of a demonstrator, the entire body and to be submitted at intervals of time to an examination on the work which has been done. In the surgical laboratory the special work embraced the study of the surgical relations of the different structures, muscles, blood vessels, and nerves, the knowledge of which, with that of the topographical relations, is so important to the surgeon and constitutes the groundwork of his skill.

As the structures of the body are continuous in substance and correlated in function, the writer has always felt in his teaching that the one intending to become a specialist in the practice of any of the branches of medicine should receive instruction in anatomy in its entirety. Study by dissection only of the parts which contained the organs or of the organs themselves which constituted his practice, gives the specialist a very imperfect knowledge of the important relations the component parts of these organs bear to the general structures and organs of the body of which they are a part. Entertaining this opinion he was the first in the history of anatomical instruction, so far as he knows, to require that students in dentistry in the institution in which he was the professor of anatomy should be required to receive instructions in the anatomy of the entire human body, and in the anatomical laboratory dissect in order the entire body. Furthermore, during the period of instruction the student was submitted to periodical examinations, and in the final examination for the degree, examination on the entire subject held a place of importance and of value in the same respect as that of the special subjects taught. It is not possible for the purposes of intelligent instruction to separate special organs of the body, as the eye, the ear, or the teeth, and their associated parts, from the rest of the body, or to destroy their important relation, hence the importance of the study of anatomy by those who engage in the practice of specialties.

In the early days of the writer's experience in surgical work importance was given by the great masters to the necessity of well-grounded instruction in the *principles* of the science of surgery—these were basic in character and preceded instruction in the practice. In the hands of the true surgeon the knife is simply an instrument, guided by the knowledge which he has acquired of the morbid conditions which involve a state of normal health, or by progressive development which jeopardizes life. This knowledge is gained by study, investigation, and the lessons of experience. The study of the etiology of disease claimed earnest attention then, as it does in this day, when by the perfected laboratories of research and the faithful devotion of able investigators, the quest for the causes and the agents of relief of destroying diseases is unremittingly conducted, and the victories achieved in the contest contribute in ever-increasing beneficial results to the well being and welfare of the human race.

## THE CARE OF SURGICAL PATIENTS.*

By DONALD C. BALFOUR, M.D.,

MAYO CLINIC, ROCHESTER, MINNESOTA.

So much has been written relative to the care of surgical patients that it may appear presumptuous to attempt to offer anything worth while in the limits of a paper on this subject. I shall only synopsize the essentials of surgical treatment as they are in vogue to-day, which will necessitate more or less repetition of well known and accepted principles. Some justification for this is found in the constant changes, minor in detail it is true, which are taking place in the conduction of surgical cases. To facilitate matters I would discuss the management of these patients under four headings: (1) Care before operation; (2) care during operation; (3) postoperative treatment, and (4) advice to patients.

### CARE BEFORE OPERATION.

A detailed physical examination and careful recording of the findings in connection with the preoperative care is imperative. The actual preparation of the great majority of patients for operation is simple and requires of them no deviation from their usual mode of living up to the afternoon previous to the day of operation, when the patient should receive two ounces of castor oil in beer and a light evening meal. A tub bath should be given, especial care being taken to avoid chilling, and the field of operation shaved. In the morning the lower bowel and rectum should be thoroughly evacuated by enemata when the preparation for the operating room is complete. This simple routine applies to the large percentage of surgical cases, while special conditions require special measures.

In all emergent cases the preliminary treat-

*Read before the Sangamon County Medical Society, Springfield, Ill., November 10, 1913.

ment should necessarily be abbreviated and usually omitted altogether.

It is advantageous in extremely fleshy individuals in which a radical operation for hernia is to be done to decrease the weight as much as possible by judicious dieting.

There are several groups of cases in which operative procedures would be of considerable risk, and in which the patient can be improved by appropriate treatment. Under this class we have:

(1) Goiters of the exophthalmic type, in which the disease is at an acute stage. The operative risk is prohibitive in these cases and measures must be attempted to quiet the exacerbation. The preparatory treatment is extremely important and yet simple, depending, as it does, on absolute physical and mental rest and the use of infusion of digitalis as a cardiac corrective. Practically all drugs and local treatment have been proved to be of little definite value. The acute intoxication must subside before operative measures are attempted. Exophthalmic goiter is never a condition demanding an emergent operation and the importance of avoiding surgical treatment during this critical period is obvious when one remembers that the operative mortality had been reduced to about one per cent. because of better preparation of patient and the proper selection of the type of operation.

In the toxic type of goiter without exophthalmos, the chief lesions are of the heart and kidneys, and this group exhibits the heaviest mortality following operation. Similar preoperative care is as applicable to these cases as to the typical exophthalmic group. The management of patients of both these types after their arrival in the hospital should be conducted with the greatest caution. The patient should have a room alone and should be shown the greatest consideration with every whim gratified if possible. We have on more than one occasion seen patients develop an acute hyperthyroidism from a definite mental irritation. A laxative should not be given these patients because of their susceptibility to gastrointestinal disturbance. About 45 minutes before operation 1/6 grain of morphine with 1/120 grain of atropine and 1/200 grain of scopolamine should be given, the combination of which limits the secretion of mucus in the respiratory tract and more or less stupifies the majority of patients.

(2) One of the most striking examples of the value of preparatory treatment is seen in prostate cases. In these the operative results have been greatly improved by the introduction of one principle, *i.e.* the preliminary drainage of the bladder. The opportunity this affords of clearing up the urine, maintaining the specific gravity, and of diminishing the blood pressure has been definitely shown in cases treated in the Mayo Clinic. This drainage is accomplished in some cases by a permanent catheter in the urethra; in others it is necessary to introduce a catheter through a suprapubic stab in the bladder. Crenshaw has shown that in the last 50 cases of prostatectomy in our clinic the average improvement during their pre-operative care was a drop in blood pressure from 166 to 145 mm. and the specific gravity of the urine maintained at an average of 1011.

(3) Severe anemias due to hemorrhage from uterine fibroids, bleeding ulcers of the stomach and duodenum, and hemorrhoids should be treated by large doses of iron, and forced feeding. An occasional case may be suitable for transfusion shortly before the beginning of an operation.

(4) Patients deeply jaundiced are bad surgical risks and if the jaundice is transitory operation should be delayed until it has almost disappeared. The coagulation time of the blood is the most accurate indication we have as to advisability of operating, but it is also true that changes in the blood vessels themselves are more or less responsible for their tendency to bleed easily. We have not seen any appreciable results from the use of the calcium salts and have been disappointed in the results obtained from experiments with horse serum.

(5) The condition of emaciated patients—particularly gastric cases with obstruction at the pylorus—can often be greatly improved in the course of a few days by increasing the body fluids; *e.g.* a quart of saline solution administered per rectum night and morning. All patients with suspected gastric lesions involving retention of food should have the stomach thoroughly washed the morning of the operation.

(6 ) Certain cases with acute infections are benefited by careful preoperative watchfulness. Active infections in the pelvis, cholangitis and certain stages of peritonitis are oftentimes better left undisturbed than interfered with when the patient's illness is due to a general toxemia and not to some focus of disease. These patients are still a subject of considerable controversy but I believe the opinion is gaining ground that if they are definitely getting over the infection it is worth while to wait for a time until some immunity is established.

(7) As regards the administration of alkaloids before operation: There is no doubt but that their use should be limited, and probably confined, to morphine and atropine. Although we are accustomed to give scopolamine to patients having exophthalmic goiter, we must admit that we believe making a routine of this practice is open to question. Morphine and atropine are given in gastric and rectal cases, in recent infections of the lung, to very fleshy individuals, to alcoholics, and occasionally to patients with heart lesions with whom local anesthesia is to be used.

### CARE OF PATIENTS DURING OPERATION.

The question of anesthesia is still a much discussed one. Ether administered through an open mask by a competent anesthetist is believed to be the most satisfactory anesthetic for the majority of cases. Ether by the intratracheal method is extremely satisfactory for certain types of cases. After the patient has been placed in the proper position on the table and while the anesthetic is being given, the preparation of the field of operation is made. The skin is cleansed by a piece of gauze moistened by benzine to remove grease and dead epithelium, and after this has thoroughly evaporated, tincture of iodine is applied, the strength varying between 3½ and 7 per cent. When this has dried, and the operative area is surrounded by towels, the preparation is complete.

For the welfare of the patient during the course of the operation nothing more than adherence to sound surgical principles is necessary. A minimum quantity of anesthetic should be used to produce anesthesia which will be just and consistent with the surgeon's work. Careful exploration, a not unduly prolonged operation, maintaining bodily heat, as little manipulation as possible, no more retraction of wound than is necessary to expose the parts,

accurate hemostasis, and a precise toilet to complete the operation, are all factors in lessening the possibilities of postoperative complications. Rarely, if ever, are stimulants necessary or even advisable during the course of an operation. It is illogical in a patient who is markedly shocked to add further stimulation to an already over-stimulated nervous system.

CARE OF PATIENTS AFTER OPERATION.

It is true that the majority of operative cases require no special care during their convalescence, and this discussion will be confined to the treatment of special groups of cases and various complications which may arise.

Patients with toxic goiter require just as painstaking postoperative care as they received before operation. It is extremely essential that these patients obtain fluid in some way as soon as the operation is completed. As a routine, saline should be given per rectum and in the serious cases if this is not retained, hypodermoclysis should be used. In patients with mental restlessness or cardiac irritability, ice to the head and precordium are probably of service. Drugs of any kind are of doubtful value; morphine, in some cases is beneficial. Practically all cases should be drained following operation for goiter, the tube being removed in 24 hours. Acute hyperthyroidism occurring after operation for exophthalmic goiter is an extremely serious condition and apparently no treatment is of any definite control over the intoxication which runs a short course terminated either by death or recovery within 12 to 48 hours.

The management of patients who have been operated on for lesions of the stomach and duodenum, including gastroenterostomies, resections, and plastic operations, should follow a more or less routine procedure. On returning from the operating room, the patient should immediately be placed in a sitting position in bed and this maintained as much as possible for several days. This facilitates drainage of gastric fluids, and very few patients object to the upright position. Hot water in small quantities should be given after the first few hours, and if this does not cause any ill effect, it should be gradually increased and the next day weak tea, broth, or albumin added. During the first 24 hours an average of 2 quarts of saline by bowel should be given to gastric cases. Occasionally oozing takes place into the stomach in some of these patients and the temporary paresis causes retention of secretions and old blood. This should be carefully watched for and if the patient is not able to vomit, gastric lavage should be carefully done with small quantities of warm water, adding soda bicarbonate if the contents are sour or acrid. The food in these cases should be gradually increased until about the time the patient leaves the hospital, when a full diet is allowed with a limitation of the heavier articles.

Another group of cases requiring special postoperative care are the prostatectomies. Here the most active attention is necessary during the first 24 hours to make sure the bladder is draining properly and that the catheter or tube in the bladder is not becoming plugged with clots. As soon as drainage is removed these patients are gotten up in order that they may not become bed ridden. Undoubtedly many patients recover by reason of this forced activity who would not have otherwise done so.

Realizing the impossibility of discussing in detail the treatment of all classes of operative cases, it seems wise to limit the discussion to a consideration of the more common symptoms and complications which arise during convalescence.

*Pain.*—Pain is a variable symptom depending on the operation, and, to a great extent, on the patient. We believe that convalescence is more rapid and more satisfactory if morphine in sufficient quantities to alleviate pain be given during the afternoon and night of the day of the operation. In very few instances will any opiate be necessary after the first 24 hours.

*Vomiting.*—The vomiting supposedly due to the nauseating effect of the ether is of no special moment. The vomiting which persists is of a different type and may assume serious aspects. Sometimes an enema will relieve this condition by setting up a peristaltic action in the intestines and a passage of gas. Washing out the stomach with 2 or 3 glassfuls of warm water is sometimes all that is necessary. In other cases washing with the tube may be necessary and in still another group, in which the condition becomes a dilatation, nothing but systematic lavage every few hours will avail. Undoubtedly many patients have been lost because this condition was not recognized, and, since the treatment is only mechanical and its efficiency so definite, little excuse can be made if a patient succumbs to such a complication. A useful adjunct in these cases of acute dilatation is to have the patient lie prone in bed with a pillow under the hips. Quite frequently this immediately relieves the condition.

*Thirst.*—Since the advent of the practice of giving fluid per rectum, thirst is not such a common complaint. In most instances, as soon as the postanesthesia vomiting has ceased the patient begins with a little hot water and if that is retained there is no further reason for limiting the supply of water.

*Gas.*—This word brings up painful recollections to many of those who have undergone abdominal operations. Drugs to stimulate peristalsis are uncertain in their effect and are not used with any frequency. Oftentimes the use of a rectal tube will relieve the patient and enematas of various kinds should be tried since some will be effectual where others fail. Of these remedies, the most commonly used are soap water, plain or with turpentine, salts, and glycerine, alum, etc. If there be marked rectal irritation, milk and molasses is very satisfactory.

*Mucus.*—Mucus in the respiratory tract is sometimes very distressing, the patient who has had an abdominal operation being unable to use sufficient muscular effort to cough it up. A simple expedient is to hold the patient upright in bed, firmly supporting the abdomen by encircling his waist from behind. Braced in this way, the patient can rid himself of the troublesome mucus with little discomfort.

*Inability to Urinate.*—Following certain operations; such as goiters, laparotomies with small incisions, etc., it is preferable to get the patient out on the side of the bed rather than to use a catheter. The use of the catheter should be limited as much as possible since infection of the bladder may occur in the best regulated hospitals. A patient makes a bad bargain in exchanging a chronic appendix or a hernia for cystitis.

*Paresis.*—When of a mild degree, paresis is of no serious consequence. It is best relieved by anemata. The more prolonged types, however, are a menace and require judgment in the treatment;

the main and, at times, difficult point to be determined is whether or not the patient is overcoming the paresis. Any active interference to relieve the condition means re-operating. This same problem arises in the cases of secondary intestinal obstruction due to an adherent loop of small intestine, volvulus, etc., and the decision rests between giving the patient a chance to overcome the obstruction or to re-operate to relieve the obstruction. As a last resort, Rutherford Morison advises giving an ounce or two of castor oil. A satisfactory method of administering the oil is through the stomach tube, after washing out the stomach. This procedure quickly settles the question and although somewhat drastic is justifiable. Should operative interference be considered necessary, an enterostomy is usually chosen and undoubtedly has been the means of saving many lives. The patient is usually in a precarious condition by the time such a step is decided upon, thus the shorter and simpler the procedure the better. As a rule, local anesthesia is employed. The distended loop of bowel is brought to view and, occasionally, the obstruction can be located and relieved. The enterostomy is best made by a modified Witzel method, and the bowel should be drained more or less slowly. The resulting fistula often closes without any further attention and, should it not, a closure is readily made later.

*Complications of the Lung.*—Complications of the lung vary according to the season of the year and quite frequently appear to be epidemic in character. An acute condition which closely simulates pneumonia is perhaps the most common of these pulmonary complications. It usually begins on the second day following operation with an onset suggesting pneumonia, and with the congestion of an early lobar pneumonia. This condition is maintained for two, three, or four days, without developing further than the primary stage of a true pneumonia and then is suddenly terminated by a crisis. The essential treatment for these cases is to keep up the bodily heat of the patient, giving them all the fresh air available. Even in the coldest weather the patient may be placed in front of an open window.

*Renal Insufficiency.*—Indications of renal insufficiency should be carefully noted following operations on the urinary tract. Accurate measure must be made of the amounts of urine voided and at any sign of failing secretion, fluids should be increased and, if necessary, sparteine, 3 grains, be given every 3 hours. In rare cases of total suppression, decapsulation of the kidneys has been done with relief of the condition.

*Postoperative Hemorrhage.*—As a rule, this condition is readily recognized but, if any doubt exists, one should make absolutely certain. Deeply jaundiced cases are more treacherous in this regard, the slow coagulation-time combined with the peculiar changes in the vessels themselves, making a secondary oozing very likely. In a few cases, we have observed undoubted benefit follow transfusion and in many cases questionable benefit from the use of horse serum. Means should always be at hand with which to perform a transfusion. Many methods of simplifying this procedure have been described recently.

*Shock.*—A true condition of postoperative shock not caused by hemorrhage, unnecessarily prolonged operations, or badly administered anesthetic, is rarely seen. When such shock does occur, saline solution subcutaneously with the aid of morphine, and camphorated oil every 2 or 3 hours will accomplish about all that can be done. In connection with shock the brilliant investigations of Crile have opened up a new and interesting field for study. The importance of the subject and its true valuation can only be determined by time and the experiments of various observers. The benefit to be derived from blocking the peripheral nerves which are encountered in an operation would seem slight and of practical value in only a small group of cases.

*Postural Drainage.*—In acute abdominal conditions we believe that postural drainage plays a very important part in the recovery of the patient. For example: In cases of perforated appendix, with peritonitis if the patient be kept well up in bed and lying to the extreme right side, he has a much better chance of recovery than if this principle is not followed. To render drainage efficient in these cases, frequent changes of the wet dressing are advisable.

*Phlebitis.*—Phlebitis is a very distressing complication which usually occurs about the tenth day and involves the femoral or saphenous vein. It is not amenable to treatment other than absolute rest and local heat. The importance of rest of the affected limbs is well known because of the association with embolism.

*Embolism.*—When embolism occurs, practically no opportunity is afforded for treatment and if there were time, we should be at a loss to know how to proceed since no one has as yet accomplished anything in the treatment of the condition. Undoubtedly there are patients who recover permanently from pulmonary embolism, and patients may live several hours and then succumb to an attack. Embolism is one of the bugbears of surgery. The accident occurs, as a rule, just when the patient and his family are happy in the belief that all danger is past. In this connection, the question arises of how long patients should be kept in bed? Our observations would not indicate that patients are in any way benefited by a prolonged stay in bed or that their being kept in bed will obviate the possibility of embolism.

### ADVICE TO PATIENTS.

The fourth point worthy of emphasis is the importance of explaining to patients recovering from a surgical operation just how to take care of themselves and what they should expect in the way of symptoms after being dismissed from the hospital. It is a mistake to allow patients to believe that their recovery will be complete in a month or two after an operation on the gall-bladder, stomach, or even the appendix. The post-operative treatment of these patients in the way of judicious living should continue for several months according to the type of operation. To patients who have been operated on for exophthalmic goiter should be carefully explained the possibility of a recurrence of the trouble, and all the circumstances of every case should be explained to some member of the family at the time of operation. If there is a possibility of hernia following drainage the patient should be apprised of the fact. These patients should also be told as explicitly how long to refrain from their usual work.

In conclusion, I would emphasize the fact that the basis of treatment of surgical patients is simplicity. The after-care should cause little worry except in the event of complications, since the work should be completed in the operating room. As

Rutherford Morison says, "Incomplete operations are never satisfactory and are more disastrous in their results than the most heroic, when thoughtfully planned and skillfully executed."

## THE TRAUMATIC NEUROSES, DUE TO ALLEGED OR ACTUAL INJURY, FROM THE MEDICOLEGAL STANDPOINT.*

By RAYMOND WALLACE, M.D.,

CHATTANOOGA, TENN.

SURGEON TO BARONESS ERLANGER HOSPITAL.

THE tremendous industrial and transportation development of the last few decades has given rise to an important and ever-increasing type of cases which demand a proper understanding and classification. They appear largely as the result of alleged or actual injury, either physical or psychic, and our professional relationship becomes of greatest importance when litigation is entered upon for the sake of securing indemnity.

The spirit of "acquisitive litigation" is not new. It has no doubt existed since the establishment of legal tribunals—when the individual has sought compensation for injury or suffering believed to be due to the negligence of others. Indemnity was sought, however, for material injury, such as loss of an eye, an arm or leg, or a broken skull, or spinal column, with definite objective symptoms that were unmistakable. But one must stand appalled to-day at the wholesale litigation based upon alleged or actual injury, where the physical evidences are slight or absent, yet where serious and permanent damage to the mind, health, and body are claimed. It would be difficult, indeed, to estimate the amount that is now paid annually by railroad and industrial corporations to claimants of this class. This very situation places upon the medical profession the tremendously important and responsible task of serving not only as personal physician to the claimant, but also as witness or expert in the courts of law when the justice and extent of his claim is determined.

The real genesis of this type of injury, from a medicolegal standpoint, dates back only from the time of Erichsen. His theory of concussion of the spinal cord as a pathological entity was purely hypothetical, yet he attempted to show that even after the slightest injury or shock there might develop the most serious forms of progressive nervous disease. It was explained at first upon a theory of disturbance of vascularity of the spinal cord, and later it was thought to depend upon multiple areas of inflammation disseminated throughout the cerebrospinal column. It has, at various times, been considered organic, partially functional, and wholly feigned. But the erroneous conclusions of this early work, which have been very largely controverted by later investigation, have, nevertheless, served as the basis, both in the lay and professional mind, for a vast number of absolutely fraudulent damage suits.

In the early '80's Page saw that Erichsen's work was without pathological basis, and that there was no evidence that a spinal concussion—comparable to the demagnetization of a magnet by a blow of a hammer, a favorite expression of Erichsen's—was ever caused by direct violence on the back or by a general shaking up of the whole body.

Dana, in 1884, gave a complete résumé of this class of cases, which, with few modifications, is accepted to-day as essentially correct. He states: "The term 'spinal concussion' is misleading and often incorrect, and the symptoms which are usually associated with that name are really symptoms of traumatic neurasthenia, hysteria, and hypochrondriasis, associated more or less with symptoms of injury to the vertebral muscles and ligaments and to the spinal nerves; that, in other words, concussion is mental shock and physical bruising." The evidences of violence which follow a railway or trolley car accident, for example, are many and varied. There may be anything from simple abrasions, jars, and wrenches, to muscular or tendinous ruptures, fractures or dislocations, nerve injuries, paralysis, and many injuries of internal organs. But rarely do corporations deny liability where physical evidence of injury is present, and such claims are usually settled out of court.

The widespread impression that the spine and spinal cord are liable, before all other parts, to meet with injury in cases of accident, accounts, in large measure, for the multiplicity of these cases in the courts today. The lawyers believe it, the laity believe it, and, unfortunately, many doctors believe it. Such cases are met with in the courts, but how rarely are they seen in the large clientele of private practice.

Countless accidents occur in private life, such as in football, in runaways, automobile smash-ups, falls from great distances—which give rise to broken bones and serious laceration of tissues, yet, because of the absence of liability on the part of others, either individual or corporation, it is rare indeed, though physical pain may persist for years, to find the development of the neuroses—the subjective symptoms of accident, which are here to be discussed.

Because of the predominating psychic factor in these cases, and the hope of receiving idemnity from someone, Hamilton has recently classed them under the term "litigation psychoses." This same syndrome has been variously designated as accident aboulia, railway spine, spinal concussion, Erichsen's spine, traumatic neurosis, traumatic neurasthenia, and traumatic hysteria.

The etiology of a traumatic neurosis does not depend so much upon the extent of injury or physical violence as upon its subjunctive reflection upon the mind of the person injured. Its development is almost entirely psychogenous. There are several factors in this development. An *intrinsic predisposition* may be present because of inherited or acquired disease which preexisted the accident. It is quite conceivable that chronic intoxication with alcohol, with syphilis, and with lead may form an unstable psychic background. Certain occupations under the stress of intense heat and noisy machinery may make the nervous system more sensitive to shock.

The natural mental inferiority of the injured one may, by designing lawyers, be attributed to injury. I have examined cases in which defective intelligence and hearing—due to adenoids and nasal polypi—were attributed to brain and cord injury from an accident. Another case of physical inferiority in which parasthesias, disturbances of locomotion, and mental inalertness—due to morphinism—were attributed to a nervous shock from an electric wire, and for which substantial damages were sought.

There is in all accidents, in relation to the individual, a certain phase which must be considered.

*Read before the Tennessee State Medical Society.

Hamilton calls this the sense of *preparedness;* that is to say, the attitude of the individual so far as expectation is concerned. The locomotive engineer may be thrown violently from his cab and sustain grave physical injury, but how often do we meet in them a conflicting hysteria, neurasthenia, or hypochondria? But the passenger, unconscious and unprepared for danger, may receive only slight physical injury, but serious nervous or mental shock.

Several years ago Prince took the trouble to collect statistics which show that there is a comparative absence of nervous disorder among those who are on the lookout, or who are consciously "taking their chances." He found that while football players may sustain almost any form of violent injury, they are never the subjects of traumatic neurasthenia or traumatic hysteria. Outten found that of 18,275 cases of railway injury among employees there were but eight cases of the so-called traumatic neuroses, or one in a little over 2,000; while of 884 injured passengers, there were 11, or one in about 76. It is, therefore, most essential to investigate in detail the physical, nervous, and mental condition of a claimant previous to an alleged accident.

The physical symptoms of severe primary shock are those dependent upon the impaired cardiac action with resultant anemia of the brain, and for a period an exhaustion of general nervous function. The mental symptoms are first unconsciousness, and later depression and psychasthenia. These latter may exist for a long time and finally lead to forms of neurasthenia and to psychoses of varying kinds—provided conditions be favorable for such development. However, the vast majority of cases which have sustained more or less physical injury, and months or years later bring suit for spinal injury with its variegated syndrome of symptoms, rarely suffer from primary shock. The neurosis which they present is largely a product of subsequent environment.

Following the pain and functional inconvenience due to the accident, the mind of the injured person begins to dwell upon the local injury, the accident itself, the unjust misfortune of his being a victim of such an accident, and the responsibility of another for his present incapacity and suffering. At this juncture, had he fallen from a step-ladder in his own home and wrenched his back, or twisted the ligaments of his hip, and no one responsible but himself, no nervous symptoms, no neurosis, would develop. Sleepless nights follow, during which he meditates upon his condition, his present incapacity, and predominating all is the thought that some one must be held responsible.

A favorable psychic environment at this period is usually lacking. Friends and relatives come forward with sensational tales of similar cases, with prognostic forebodings. They point out new and undreamed-of symptoms and pains, which are soon acquired and become very real. It is insisted that he is unable to work. He may attempt his former occupation, but impressed with his incapacity, he returns to his bed more discouraged and pain-stricken than ever. The moment the question of damages arises, the dominant or nearest relative usually exerts a most extraordinary and dangerous influence. A compelling sense of injury and justice leads them to seek redress. The relatives have enlarged their understanding by discussing the case with doctors and lawyers, and the conviction of injury is strengthened and intensified. Subsequent examinations by physicians and conversations with lawyers inflame his mind. He now exaggerates his symptoms. He speaks of "horrible nights," tearing pains, bloody urine, constant headaches, impotence, obstinate constipation, vertigo, frightful weakness.

There now enters the final and characteristic factor of an accident psychosis—not the pain he suffers; not the memory of the accident; not the distress at his incapacity to work, but the insatiate and thought-consuming desire for money as a compensation for it all.

The detection of the various forms of accident psychosis as differentiated from organic injury is not always of easy moment, and in many cases learned physicians will differ and appear as experts on opposing sides. But this is unfortunte. The almost mathematical accuracy with which a brain or spinal cord injury, a hemiplegia, a paraplegia, a monoplegia, a myelitis, a sclerosis, a neuritis may be diagnosed, lends little excuse for these professional bickerings on the witness stand. A differentiation between organic lesion and functional disease, when a careful examination of the claimant may be had, should be absolutely possible in the vast majority of cases.

To illustrate a few of the typical forms of traumatic neurosis, permit me to report briefly a few personal cases. Certain seemingly unimportant details are given because of their bearing upon the psychic environments.

Case I.—J. F. T., male, white, aged 42, Fort Payne, Alabama; examined Sept. 12, 1910; occupation engine hostler A. G. S. Ry.—salary $52.50 per month. First worked 5 months for A. G. S. Ry. in 1904. Previous to alleged accident he had been working for them for 8 months. Went out on a local strike twice. Alleges to have been injured between 11 and 12 P. M., November 30, 1908. He was on night duty and was assisting a wrecking crew to re-rail an engine. He states he was under the wrecked engine on his knees attempting to turn a replacer around, when the engineer threw a lever forward and an eccentric link struck him upon the lower part of the back and right hip. He states that he crawled out from under the engine by himself and in a short time went home. Dr. W. saw him next day and stated there was a bruised area over the left hip. Returned the following night to go to work, but laid up on boiler and hired two men to do his work. The following morning he stated he had to be helped off the engine and to be carried home in a wagon. He states that he couldn't walk, and that the next morning he passed bloody urine and had done so up until about a month ago, a period, you will note of nine months from the date of the accident. He was taken to Birmingham 24 days after the injury, and he states he frequently passed blood while there. Dr. S., who was present at the examination and who was attending surgeon in Birmingham, asked why it had never been found by the attendants. He replied that he did not call attention of the nurses and doctors to it. Spent several weeks at the hospital in Birmingham and was able to walk to his home from the train upon his return (a distance of some nine city blocks). Admits walking in Birmingham without a cane or crutch, but also states that he has never walked a step without a limp since he was hurt and that since his return from the hospital he has grown steadily worse. For nearly thirteen months he has now lain about the house, most of the time without a physician, but with the typical environment above described. In his own words, he now complains of pain in back and hip and nerves. Says he gets weak and shaky and nervous. Says he weighs much more now than he did in Birmingham. His appetite is good. The subsequent physical examination, which I will not detail, showed absolutely no injury to spinal column, nerves, bones, muscles, or heart. He complained of pain at any point on the body you made pressure. His face had the dogged look of one trying to deceive. In February, 1911, his suit for $15,000 was tried before a jury of his fellow-townsmen, many of whom had been forced to help support him and his

family for more than a year while he was waiting for his suit to come to trial. He had to be assisted to the witness stand by two men—with the greatest caution—and apparently with severe pain. But as the direct and cross-examinations proceeded, and he forgot himself, he crossed and recrossed his legs, stooped over and handled himself generally as a man without pain. After the facts of his simulation were presented by physicians—and after they had sworn that he was a fake—with absolutely no physical injuries or evidences of injury, a verdict was returned in about thirty minutes for $1,500.00.

This was a typical case of a traumatic neurosis, or, as Hamilton puts it, "a litigation neurosis." His predominating physical symptoms were those of neurasthenia—not caused by an accident, but by his subsequent mental environment and attitude toward the accident.

Before I leave the form of traumatic neurasthenia, let me illustrate by reciting a case where suit was not brought, where an earnest effort to regain health existed, and where recovery resulted.

Case II.—F. P., expressman, male, age 63, was in an express car when it rolled over an embankment. He was severely shaken up and bruised. After he recovered from his bruised eye and legs and arms, there persisted a dull, aching pain in the lower part of his back. He became restless, irritable, and morose. He could not sleep nights. He could not walk downstairs. He was certain he could not return to his work for months, and perhaps never. It was a typical traumatic neurosis—a neurasthenia with melancholic manifestations. He was given electric and vibratory treatment to the spine, some nerve tonics were administered, but he was constantly assured both at home and by his physicians that he would permanently recover and would be able to perform many more years of useful work. Finally, the relationship of his own mental attitude was explained to him in detail and he was urged to assist. In two months he returned to his work, and for the first few weeks he felt he could not continue, but with his own will-power and repeated assurances from his physician and family, he continued, and for nearly three months he has now performed his former duties with practically no inconvenience or suffering. This is an illustration of the usual recovery of these cases—in a reasonable period of time—when the factor of litigation for the purpose of securing indemnity is not present.

Let me now detail a typical and remarkable case of traumatic hysteria which I saw the latter part of 1910.

Case III.—J. W., colored porter, age 22, married one year. States that on March 4, 1910, while at work as porter and while dusting, he was struck by a live electric wire on the back of his head. He states that it knocked him down and he became unconscious. He says he remained in bed three days and then returned and tried to work for two days, when he found himself unable to continue. He returned home and was later carried to his mother's home, where he has remained until the date of this examination,—a period of about nine months. His physician stated that there was a discolored area on the back of his head, which disappeared upon the application of salve. He complains now (his own words) of headache all the time, eyes feel badly; states that he eats and sleeps very well, bowels move well every day; has no fever or sweats. His chief complaint is that he suffers from certain "spells"—which come on at any time, day or night. Dr. T., his physician, stated that he has seen him in probably a hundred of these spells. Upon examination the man was well nourished, with good, but slightly rapid, pulse, temperature normal, stomach, bowels and lungs normal. An area over the back of the neck—a little to the right—he stated, upon pressure, caused much pain. This was the area of the electric burn or shock. Reflexes were all somewhat exaggerated. Pupils normal. The man appears exceedingly nervous and trembles considerably. At irregular intervals he sighs deeply. During the physical examination, he had one of the "spells" already mentioned, in which he groaned, became rigid, and fell. He was caught and laid on the bed and remained there for perhaps two minutes, during which time he would not respond to questions. Within a few minutes we lifted him to his feet and he walked about the room in a dazed but belligerent condition. We then seated him in a chair, where he sat still, in a dazed condition for a few seconds, when, distorting his face and doubling up his fists, he moved indefinitely about the room. He was then sent into another room, where he lay down upon a couch. In about five minutes he responded intelligently to questions, and said he felt badly and that his head hurt.

Now, this negro never had any of these hysterical convulsions before the alleged burn, and his case was undoubtedly a traumatic hysteria. He and his entire family were greatly impressed by the seriousness of his condition, but more especially by the liability of the corporation for whom he worked. I advised settling the case out of court, for I was positive he would have an hysterical seizure on the witness stand, and yet I was likewise positive that the seizures would disappear as soon as the case was settled. It was compromised for some $1,500, and the boy's father told me only recently that he was perfectly well, working every day, and has not had a single convulsive attack since he received his money.

I have recited this case in detail, for it is so typical, and the prompt recovery after the award of damages is so very frequent. A prominent lawyer, after securing a substantial verdict in a case of traumatic hysteria, recently remarked to me that "a good round verdict does more to cure these cases than a dozen physician's prescriptions."

Some eighteen other cases, presenting various phases of the traumatic neurosis, I shall report later in a more comprehensive paper, but I believe I have sufficiently illustrated at least two very typical forms.

Another phase of intense interest is that of pure simulation. This term should be employed only when the individual purposely and consciously attempts to deceive us. He may wilfully exaggerate such symptoms as do exist, or represent disease conditions to exist which either preexisted the accident, or which do not exist at all. In fact, he may present symptoms or physical signs due to an accident which never occurred. The attempt to deceive must form an integral part of our conception of simulation.

This paper is necessarily curtailed and incomplete, but there is a wide field for thoughtful investigation in the traumatic neurosis, and the profession must more fully prepare themselves for the judicious handling of these cases. The medicolegal phases must be better understood, so that reputable physicians shall more closely agree upon diagnosis and prognosis when appearing as sworn experts before the juries and courts of the land.

## ECLAMPSIA, WITH TOTAL ABSENCE OF ALBUMIN, BUT GENERALIZED, HARD EDEMA. (PURE CHLORIDE-RETENTION?)

By CECIL KENT AUSTIN, M.D.,
PARIS, FRANCE.

*"Toute femme enceinte doit se soigner, et se laisser soigner."*
(Bouffe de St. Blaise.)

It is anything but easy for a rational mind to get the upper hand of the feeling that since childbearing is a normal, physiological process it ought, at any rate in the immense majority of instances, to take

place without mishap. And yet, what does experience show? That never was there conviction founded on less fact than this one. Not only is it exceptional for a physician to come through with a confinement case without something going wrong with mother or infant, but serious accidents of dystocia are of common occurrence. It is true, cases of infection can now be almost ruled out—certainly in the better classes of the community; thus personally, in a practice of now over twenty years I have never seen any puerperal fever, and have only had one breast abscess. This occurred in a patient who was confined in the country, and whom I had to leave in charge of an elderly and quite ignorant nurse—practically the only typical Gamp with whom I have ever had to deal. But the other forms of dystocia, eclampsia, incoercible vomiting, contracted pelvis, placenta prævia, fibroids, hydramnios, breech-presentation, velamentous insertion, cord pressure, phlebitis, infantile malformation, uterine inertia, etc., etc., present themselves with a frequency that is absolutely disconcerting. I am quite willing to admit that my own experience in this connection must have been exceptional. I have never made any special bid for confinement cases, and have always practised in a social aggregate in which childbearing is looked on with pronounced disfavor; my obstetrical range has, consequently, been by no means extensive. Yet my dystocia percentage, if added up, would certainly reach 25 to 30 per cent. I almost hesitate to give the figures, so unnatural do they appear. I have often wondered in what particular I can have so grievously offended the Gods, to have been so vindictively pursued by their malevolence as this. There was actually a period, not long ago, when I had five serious cases of dystocia in succession! In fact, the only accident that I seem to have escaped is that crowning calamity of all, sudden death from embolus during postpartum, due to unsuspected periuterine phlebitis, although this has occurred twice in my immediate *entourage*, one relative falling back dead on the doctor who was auscultating her for pulmonary symptoms caused undoubtedly by lesser, premonitory emboli. If every physician's experience in obstetrics were to resemble mine, the grounds would be sufficient for deserting this noble profession and returning to humanity's original occupation, tilling the soil. Fortunately such is not the case, and most practitioners manage to get along fairly well in their obstetrics, in one way or another. But still, the truth remains that which is expressed in the maxim at the head of this article, and which medical men will do well never to lose sight of, otherwise they may be exposed to disagreeable surprises similar to the one now to be reported.

It is probable that the majority of physicians, with a primipara under their charge—healthy, well put-up, surrounded with every comfort, pelvic conditions normal, child well-placed, and urine tested every two weeks—would feel quite easy in mind. My patient presented all of these points, and never felt better in her life than the day before labor; yet right in the middle of it, luckily when dilatation was nearing completion, she suddenly had a typical attack of eclampsia, which was followed by a second before I could get hold of a confrère to help extract the fetus. Trouble began at 3:30 p. m., and labor was over by 5:30; but the patient had four more attacks before midnight. After that time, however, recovery went through its course without incident, and to-day mother and child are in excellent health, the only traces left being certain lapses of memory in the mother. This event destroyed my last particle of trust in the *mulier parturiens*, whom I henceforth look on as capable of *anything*.

This patient, however, presented one feature, to which reference has not yet been made, but to which the attention of brother practitioners is earnestly drawn, as I believe it to be practically unknown to the general medical world. The urine had, as mentioned above, been carefully tested every two weeks, and no sign of albumin had ever been found; and I may say at once that all tests made subsequently to the eclampsia-period proved likewise negative. She had enjoyed the very best of health during the weeks that immediately preceded labor, and, in particular, on the day before the birth of the child, had taken quite a long walk, upwards of two miles, though she admitted having been somewhat incommoded by her increased size and weight. Questioned later on, she could recall neither headaches, disordered sight, sleeplessness, unusual dyspepsia or constipation, nose-bleed, skin symptoms—in short, none of the minor warning-signals of the autointoxication of pregnancy. Her arterial tension had naturally not been taken, as she seemed so well; but after the confinement it was found to be normal. But she had appeared, toward the end of pregnancy, to put on weight in a markedly unusual manner. The fact had struck me; but as the increase in dimensions was absolutely evenly distributed over head, body and limbs, as there was this *total* absence of symptoms of intoxication and albumin, and as there were no apparent signs of ordinary edema—the surface of the lower limbs remaining absolutely elastic and the finger leaving not the slightest impression—I had laid the condition to a real augmentation of tissue (the patient was at an uncertain age, about 35, and had previously been rather thin, but with a very large frame, almost that of a man).

It was in this particular that my knowledge was deficient; I did not know that cases of this sort, though very rare, have been reported before—cases of generalized, hard edema, without albumin, ending in eclampsia. So it is with a view of calling attention to this pitfall that I have made this frank confession of shortcoming. This question of eclampsia has changed altogether since the days when I was a student, and the whole duty of man in the circumstances consisted in letting a few drops of nitric acid slide down the side of an inclined glass; the physician who limits himself nowadays to these maneuvers exposes himself to dire awakenings, since in addition to the form of autointoxication without albumin just mentioned, there are also others where the albumin is lacking before the attack, or only appears after it, and where even this quite peculiar edema is not present to warn the medical attendant, who has then nothing but the minor symptoms and increased arterial pressure to put him on his guard. When I first began to practise it was considered ample to make a urine test once a month; now it is cited as "very frequent" to test twice or three times a month; yet the same writer warns the reader that some cases of eclampsia develop very rapidly, *even between two tests!*

The conclusion that imposes itself is, that to look on a pregnant woman as a woman carrying out a normal function and to be interfered with as little as possible, is neither more nor less than a mockery; she is, on the contrary, a woman surrounded

by risks of all sorts and descriptions, one that cannot be too closely watched and studied. This wide subject of the autointoxication of pregnancy is one that the busy practitioner, who has been in the field for a certain number of years, should familiarize himself with afresh in some recent and trustworthy monograph; it is probable that therein he will find not a little that will prove new to him.

About three hours after delivery my patient recommenced her attacks of eclampsia. I thereupon bled her, and was never more generous in my life; I had never lost a patient in labor, and was not anxious to begin with the one in question. She had one more attack after that, but that was the last one. The next three days we kept her on a water diet, and she passed perfect *floods* of urine, her body steadily decreasing in size and her outlines resuming their normal appearance—though it was ultimately seen, two months after the confinement, that her weight had increased considerably since marriage, as is so common.

Subsequent reflection on this case—which naturally made an indelible impression on me, as I have, I believe, never been so absolutely thunderstruck in my existence as when I saw this woman, whom I looked on as in perfect health, go off into an eclamptic fit—has led me to wonder whether cases such as this do not in reality consist in *chloride-retention* purely and simply.

20, Rue Chalgrin.

## THE CAUSATION OF DREAMS.

By H. RAHMET, M.D.,
Cairo, Egypt.

There are many theories for the interpretation and causation of dreams. Professor Ladd says that the dots, lines, and splashes that appear in the field of vision when the eyes are closed determine the form and character of a dream. Montaigne holds that dreams are the true interpreters of our inclinations. Freud of Vienna maintains that a dream expresses the fulfillment of a wish. The theory of Ladd can modify but cannot explain all dreams, for the latter depend for the creation of their images on all the senses combined and not on the sense of vision alone. Montaigne's theory and that of Freud are allied; the corollaries of both are more or less similar, for the fulfillment of a wish and the interpretation of the inclinations are almost the same. However these theses do not explain all dreams; they explain a certain class only. The horrible dreams and nightmares, when one feels hurled from high cliffs into bottomless chasms, or terribly mutilated from accidents, surely cannot be the fulfillment of one's desires or the interpretation of his inclinations; no sane person will have such desires unless he is in a suicidal mood, and when he is in such a state he is not in the normal or rational condition. Again we have dreams that are prophetic in tenor; they also cannot be explained by the said theories. Hence the causation of dreams may well be studied under the following headings, viz.: (a) the discordant activity of isolated brain cells and centers during sleep, and (b) the telepathic influence of individuals or objects exerting a specific affinity on the sleeper.

In studying the class of dreams the causative factor of which is the discordant activity of isolated brain cells and centers, it is well to have a cursory glance at the psychophysiological processes of the mental phenomena. The mental phenomenon comprises the intellectual, emotional, and the volitional phases; the former two come under the domain of sensation, the emotional being the more complex; these two phases form the basis of all feelings, for the latter are the final stage of the sensory impressions. Volition, on the other hand, is the starting point of all motor activities. Feeling is the sum-resultant of the impressions transmitted by the peripheral nervous system to the brain; volition is the outcome of the elaboration of these feelings and the execution of the results in an objective sense.

The sensorimotor or kinesthetic areas are the site of these elaborations; our mental faculties depend on the impressions derived from without through the senses for the material for the intellectual phenomena. Sensation is the simplest mental operation; it is the conscious reception in the brain of the impressions communicated from the external world. Perception is the result of the different sensations thus obtained; in other words, it is the grouping together of the different sensations. Mentality is further carried on in a more complex nature to give rise to conceptions. It will thus be seen that a concept is built up of perceptions and a percept is made up of sensations. Every mental process leaves an indelible effect on the brain cells affected; from these unerasable marks representative imagination or memory is obtained.

One clearly sees that all our actions in the waking state are the outcome of the volition which in turn is the fructification of the impressions from without; we rely on memory as a faithful reservoir for the reproduction of any past event. In the state of sleep the functions of life are partially dormant, although the heart, respiration, and metabolism go on on a reduced scale. In this latent condition the sleeper and his component structural cells are reduced to a state of unconsciousness. Now and then not all the brain cells are in an unconscious state; this condition gives rise to the category of dreams under consideration whereby varied images and phantasmagoria are invoked. Matter is indestructible; energy is a product of matter hence it also is indestructible. The effects of energy are indelible, though transformation is possible; the production of images and impressions on the brain cells and centers, is an effect of energy; hence these impressions are likewise indelible so long as the receptacle, the cells, exists, though they might lie in a dormant state in the backgrounds of memory. In dreams different cells of different centers are in either a conscious or semi-conscious state; the dormancy of many previously received impressions is temporarily suspended; the activated cells reflect their stored impressions.

A complete image in the waking state is received by different cells and centers, the more complex the image is the more cells and centers are required. To reproduce the same or its prototype, the different cells and centers are appealed to under the efforts and harmonious control of our intellectual capacity. But in dreams only a part of the cells and centers concerned in the reproduction of the complete image are awake; hence they reflect only a part of the whole and give an incomplete image of the original. If different cells and centers of different images are simultaneously awake and active, they produce through this combination a new picture composed

of sections of the different images previously perceived but corresponding to none. The more the cells and centers of a real image participate in the creation of the dream picture, the more the attributes of that image preponderate in the new picture and vice versa. Suppose that the images (*a*), (*b*), (*c*), (*d*), (*e*), etc., are separately perceived by a person through the five senses modified by heat, cold, form, weight, quantity, and density. Again suppose that in a dream the same person sees only a part of the attributes of each of the said images; these different attributes which he sees combine to generate a new picture; this conglomeration of partially reflected impressions forms the network of the dream the distortion of which is the direct consequence of the proportional activity of each image-center and its cells. The more variegated and distributed are the cells and centers participating in the dream-picture, the more distorted the latter will be.

Drug visions and hallucinations fall into this category. The sedatives inactivate special cells and centers, *i.e.* put them in an unconscious state; the unaffected cells and centers reproduce only a part of the original image; hence a condition similar to that of dreams is induced. Stimulants, on the other hand, excite dormant cells and centers; the impressions of these evoked cells and centers combine disproportionately with others and give rise to conditions similar to those of dreams. Heavy, indigestible meals before going to sleep, often give rise to dreams; their action is after the drug theory. Anemia and congestion of the brain might bring about dreams in a similar way to drugs. The auras, visions, and hallucinations of epilepsy belong to this category; the prodromal effects of the coming storm excite some of the cells and centers thereby giving rise to the aura; the effects of the same brain storm in the height of the attack and in the subsiding stage bring about the illusions.

Telepathic dreams differ entirely from the others in their causes and effects. They portray actual events, the effects of which might be realized only later; their prophetic trend is sometimes fulfilled to the letter. These dreams are objective and not subjective; their contents are communicated to the dreamer through the propagation of ethereal waves of some sort, in the same way that light is transmitted from the different heavenly bodies. In all motions we must have a proper stimulus and a medium to transmit the waves; for the perception of the same, there must be a receptacle to intercept and interpret the waves expedited by the original stimulus. Hypnotism exhibits these traits to perfection; the hypnotized, though with closed eyes, sees and reads through the hypnotizer; he also sees and interprets the thoughts of others than the hynotizer; crimes and hidden cadavers have been discovered through Mesmerism. The hypnotized is in one place and sees, with eyes closed and with no visible medium of communication, things away from him; it is because he is in a favorable condition to propagate certain waves to the outside world through certain media and to receive and interpret waves passing through space. One might safely assert that every existing cell, molecule, and atom emits specific waves; the emanation of radium rays exemplifies this argument. Occult science might similarly be explained. Somnambulism is an allied condition.

Wireless telegraphy and telephony are a modification of this principle; a certain apparatus receives and transmits our thoughts by creating and propagating certain waves of specific length and vibrations; these same waves are intercepted and interpreted by a specific apparatus. Thus we see that our thoughts are transmitted from our brains through the motor tracts to the wireless apparatus to be transmitted to another from which the thoughts are transmitted by the sensory tracts to the sensorimotor areas of another person.

Can there be no other channels to transmit our thoughts to the external world other than our known motor tracts? Are there no other media for conveying these thoughts except the wireless apparatus? Surely there is, for hypnotism, occult science, and somnambulism are perfect examples. The physiological functions of the frontal lobes of the cerebrum are but vaguely known; some day they may be developed and reveal hidden wonders; at present they are likely in a latent state. A day might dawn when we might easily read the thoughts of each other by applying a special mask or apparatus to intercept and interpret the waves emitted from the brain as a sequence to the activity thereof.

The existence of telepathy is indubitable; it has appeared in history in many guises, such as witchcraft, magic, augury, etc. As previously supposed, every cell emits specific vibrations; these are propagated by ethereal waves; the interception and interpretation of these waves require a specific medium. Sleep under special influences (probably some chemical affinity) renders the sleeper a favorable medium to intercept and interpret the telepathic waves. The latter may travel from non-living to the living; these waves may likewise pass between living organisms of different classes, such as between a dog and his master. Elements in the nascent state have greater affinity to combine than those in other states; this affinity is selective, *i.e.* elements have greater affinity for some than for others; this affinity might play an important rôle in the interception and interpretation of the telepathic waves.

Why cannot a person when asleep be in a state similar to that of hypnotism? Once in that state, he is a fit receptacle to intercept and interpret the telepathic waves. A person at a distance concentrates his thoughts on another; this concentration generates specific vibrations which travel as ethereal waves; the person (the object of the thought-concentration) is by some imperceptible currents rendered a favorable medium to intercept and interpret the special telepathic waves that give rise to the telepathic dreams. By the same strong concentration of mind the image of the person or object thought of might be conjured; this process entails the sending of special waves to the object of the thought-concentration; from this a reflection is made to the seat of the original stimulus where the object is seen.

In conclusion, it will be seen that the two theories advanced above are at the root of all dreams. The theories of Ladd, Montaigne, and Freud come within the compass of the theory discussed under (A), for they are but a phase of the partial brain activity in the unconscious state. A person longs in the waking state after something beyond his reach; the image of that something is indelibly imprinted on the cells and centers of the brain; these same cells and centers might become

active while the person is asleep, the link of association filling up the gaps as a complement; by the activity of these cells and centers a dream is produced, which, modified by the links of associations, more or less corresponds to the desires evoked in the waking state. This process, however, clearly comes under that part of theory (A), which runs thus: The more the cells and centers of a real image participate in the creation of the dream picture, the more the attributes of that image preponderate in the new picture and vice versa. The image of the desires evoked in the waking state corresponds to a real image. The dreams sometimes referred to as prophetic come within the domain of the telepathic theory. There are dreams of a mixed nature; these are composed of the elements comprised in (A) and (B). Among the laity there is a variety of dreams called apparitions; these the common folks attribute to spirits or ghosts; however, they can easily be explained by a combination of the theories adduced under (A) and (B).

## LICHEN PLANUS OF THE GLANS PENIS: ITS TREATMENT WITH ROENTGEN RAYS.

By FRED WISE, M.D.,

NEW YORK.

CHIEF OF THE DERMATOLOGICAL CLINIC, BETH ISRAEL HOSPITAL; ATTENDING DERMATOLOGIST, VANDERBILT CLINIC, COLLEGE OF PHYSICIANS AND SURGEONS, COLUMBIA UNIVERSITY; VISITING DERMATOLOGIST, MONTEFIORE HOME.

THE *x*-ray treatment of lichen planus in general, and of the hypertrophic, horny, and verrucous types of the disease in particular—the latter usually circumscribed and limited in extent, is not a new therapeutic suggestion. The great majority of cases of ordinary lichen planus respond to the usual internal and external therapeutic measures, the time required for a cure varying from weeks to months. Frequently we encounter unyielding, circumscribed patches of the disease, which persist in spite of all our efforts with appropriate medication, both external and internal. Such patches may be located on the shins, on the back of the neck, on the wrist—in fact, on almost any part of the body. These persistent patches usually respond, readily enough, to radiotherapy. As in the medicinal treatment of the disease, the time required to bring about the complete resolution of the patches with the *x*-rays, is very variable.

It is a well-known fact that the glans penis is one of the areas of predilection for lichen planus. In this locality the disease has been known to persist for months and even years.

Recently I have had occasion to observe, in private practice, three cases of lichen planus on the glans penis. In one of these the eruption disappeared under external treatment and arsenic. The other two cases, however, proved quite refractory to ordinary measures, necessitating the employment of *x*-rays to bring about a cure. Brief histories of these cases follow.

CASE I.—Mr. N. S., aged 36, referred by Dr. J. J. Asch, applied for treatment on June 25, 1912. For several months past he had had an eruption on the dorsal surface of the glans penis, which, aside from the cosmetic effect, caused but little inconvenience. At times there was moderate pruritus. The lesion consisted of a patch composed of an aggregation of closely set, reddish-violet, glistening, irregularly rhomboidal, flat topped papules. The prepuce being absent, the surface was quite dry. No other evidence of lichen planus was present on the body or on the mucous membranes, at the time. But a few weeks after his first visit, the patient presented a few small, shiny papules on the back of the hand, near the thumb, which proved to be typical papules of lichen planus. After a somewhat prolonged course of arsenic, together with external applications, the lesions disappeared.

CASE II.—Mr. J. F., aged 72, referred by Dr. J. J. Asch, consulted me on April 4, 1913. The entire glans penis was the seat of a glistening, diffusely colored, dark red patch, smooth and free of scales. It had persisted for six months. This patch was rather sharply circumscribed; close inspection showed evidence of a confluence of numerous large flat papules, the edges of which had coalesced, resulting in a smooth plaque which resembled chronic, circumscribed eczema. Pruritus was slight. The rest of the skin and the mucous membranes were free. A month's treatment with the usual external and internal remedies failed to make any impression upon the lesion. I then gave the patient five short *x*-ray exposures, resulting in a complete disappearance of the patch.

CASE III.—Mr. J. S. F., aged 53, consulted me on April 17, 1913. The left half of the glans penis, as well as a small area behind the corona, presented a glistening, dark red area, which was smooth and free of scales. This patch closely resembled that of Case II, excepting that I was unable to discover any signs of the confluence of pre-existing papules. The rest of the skin and the mucous membranes were free. I made the diagnosis of chronic circumscribed eczema in this case, prescribing the usual remedies. The patient was compelled to leave for Chicago on the following day and I advised him, should he see no improvement after a lapse of a week or so, to consult Dr. Pusey of that city, and suggested that *x*-ray treatment might be advisable. Dr. Pusey wrote me that the patient had consulted him and that he considered the lesion to be lichen planus, not chronic eczema. A few weeks later, under date of June 2, 1913, Dr. Pusey again communicated with me and I take the liberty of quoting from his letter. "Our patient, Mr. F., is free of the eruption and I write to you again about him, because of the lichen planus question. It seems to me to be a case of lichen planus, as I think a good many similar cases of sharply defined patches of balanitis are lichen planus. He has gotten well under a few *x*-ray treatments and an ointment of phenol, mxv; hydrarg. ammoniat., gr. xx; zinc oxide, 5i; vaseline, 5i. Mr. F. told me that he had seen you only once, but the case is of enough interest, I trust, to allow me to impose upon you with it, once more." This letter speaks for itself.

In the light of our present-day knowledge of radiotherapy, enabling us to administer exact dosages of *x*-rays, this brief report cannot be said to possess much of scientific value. At the time these cases came under observation I was still administering the unmeasured, divided dose *x*-radiations, so that even exact data regarding the quality and quantity of *x*-rays, based on the treatment of Case II alone, would be of no value. Still, it is of interest to note that such cases get well even with the cruder methods of repeated and divided exposures; that good results are obtained far more rapidly than with the older methods of treatment, that the use of disagreeable applications is obviated, and, finally, that the cosmetic results, if sufficient caution be exercised, leave nothing to be desired.

828 LEXINGTON AVE.

## A STANDARD EDUCATIONAL QUALIFICATION FOR THE ANESTHETIST

By RAYMOND C. COBURN, M.A., M.D.,

NEW YORK.

THE last word has not been spoken on the anesthetic. In practically every medical as well as surgical periodical anesthesia, anesthetic, or anesthetist is given continually increasing space. Recently, lay publications have also entered the field, and in the writing of articles on this subject there

is no end. Twenty years ago the question was considered practically settled; to-day it is one of the most muted of the hour—the most diversified in theory, in practice, and in results. Certainly this is not as it ought to be, but verily as it is. As a consequence, often the patient, the physician, nay even the surgeon himself, dreads the anesthetic more than the knife. Anesthetic results have not kept pace with achievements in other fields, and so they are now projected in the limelight. Both strange and startling are the disclosures! Little or no instruction in the administration of anesthetics in medical colleges, and the meagre instruction that is there so sparingly and sporadically dispensed is usually by specialists in *other* fields. No such instruction nor experience in internship in an increasing number of non-interne anesthetist hospitals. To-day, many a young surgeon, using the non-medical anesthetist, finds himself, as the only licentiate, in the anomalous position of being, both in the eyes of the law and before the bar of public opinion, responsible for that in which he has had neither instruction nor experience. Yes, in one of the most learned of the professions, a member legally and literally supervises and instructs, although he himself has had neither instruction nor experience. If this were politics the cry would be Tammany, yet, since it is science, it is only history. But, it is often pertinently asked, is it not *legal* for the *nurse* to administer the anesthetic? Yes, says the Attorney General of the State of New York, *provided the surgeon is present in the room and supervises its administration, thereby becoming the responsible party.* On the other hand, it is just as relevant to ask, is the surgeon usually present in the room during induction—the most dangerous stage—and what percentage of proficiency does it add to, or detract from, the actual surgery, if he supervises the administration of the anesthetic while he is operating? And if the administration is not so supervised throughout both the induction and operation are even the mild exactions of the law fulfilled?

Side by side with this development of the non-medical anesthetist another, the senior member—if you please—the Captain of the surgical team, presents an antithetical, yet highly interesting and relevant development. Surgery has long since been regarded as a specialty, and great has been the reward, both in fame and finance, justly bestowed on those who neared the pinnacle. Here instruction, training and experience have been considered absolutely essential. The non-medical surgeon belongs to a bygone age. In fact, so basic and fundamental are considered the indoctrinated and experiential qualifications that an extra year's work is now proposed for the embryonic surgeon. Truly, if it is for the protection and best interest of the patient to elevate the scientific qualifications of the Captain of the surgical team, it is inconsistent, to say the least, to lower simultaneously those of a team-mate.

It is unfortunate that there has been such a widespread and persistent advocacy of a certain method of administering ether because, writers allege, that even in the hands of the unskilled it is safe, for, as a consequence, a part of the profession, at least, has now come to look complacently upon the matter of entrusting the anesthetic to those from whom not even any appreciable degree of skill is exacted. Nor is this all; these same writers condemn nitrous oxide, not because of its physiological, anesthetic effect, but because *its* administration requires skill. They seem entirely oblivious of the fact that the law of supply and demand operates here as elsewhere, and, if there is not a sufficiency of skilled anesthetists, it is only because there has not been a sufficient demand for such. The non-medical anesthetist, having spent less time and capital in preparation, can render service for less remuneration than the medical anesthetist. Accordingly, the economic factor has become dominant in this development. A new standard is being established for the anesthetist, and, it is said to the shame of the whole profession, that standard is an absolute abolition of the educational requirement—the very standard the Captain of the team is seeking to elevate for his peers. The standard herewith proposed is not economy, but proficiency; its foundation is not sex, but science.

It would matter little, indeed, if the evil effects of the present stage of this development were confined to the profession, but—there is the patient whose interest is supposed to be paramount. If one is to believe the literature of the day it requires only a cursory examination to show that the selection of both the anesthetic and the anesthetist is not always based upon that consideration. If your credibility concerning this statement is aroused, search the literature yourself and learn how frequently it is recorded there that the surgical patient is weighed in the balance with much less than "thirty pieces of silver!" It is a matter of commendation that so many have the courage to state it so frankly!

Since, on final analysis, the patient's interest *is* paramount, and since there are so many open confessions that it is not always so treated as regards the anesthetic and the anesthetist, and since the anesthetic and the anesthetist are so indissolubly bound together that it is practically impossible to disassociate them, is the time not meet for the different factions of the profession to confer and formulate a plan whereby the patient's interest may be as well safeguarded in this, as in the other fields, and, at the same time, give all who are competent to anesthetize a fair and free hand to pursue this calling without molestation or degradation? Let us lay aside our prejudices, and, if needs be, our personal interests, and view this in the same light and through the same glasses, that we do other professional fields, for there appears no valid reason, necessity, or even excuse, for making this specialty a unique exception.

Our present system of professional education does not tend to qualify the medical anesthetist adequately. To repeat: deficient collegiate instruction, and often no training in internship, so that even the graduates of many of our largest hospitals are wholly unqualified, both theoretically and practically, to administer anesthetics or supervise their administration. This does not meet the demands of the hour. Recently the Ohio State Medical Board requested the legislative committee of the various state medical societies to take some definite action regarding an effort "to amend the Medical Practice Act so that the state board will be able to pass upon the qualifications of licensed physicians who elect to practice in any of the specialties." If special licenses or degrees are to be the future requirements within the profession, that of the anesthetist ought to be among the first.

For the non-medical anesthetist there should also be a standard, educational requirement, for this a recognized specialty. On this view there ought not

to be a dissent. Just what this requirement should be is a matter of great diversity of opinion. Some strongly affirm that it should be nothing less than the full medical course, while others just as firmly adhere to the belief and practice that the nurse's training, plus some anesthetic instruction, is all-sufficient. Some adhering to this latter practice claim to base it upon sex. But, if the anesthetic mask in the hands of a man, *per se*, tends to produce a detrimental effect, what must be said concerning the distorted vision of the patient contemplating his grim-visaged surgeon, standing over his prostrate body, eager for his gory task, brandishing in one hand a keen cutting knife and in the other a glistening saw! Would not the logical and consistent arrangement be to place the most dangerous weapons in the hands of the gentle nurse, who, by nature and appearance, has a greatly mollified tendency towards inflicting physical injury? And would not this idea, completely and consistently executed, entirely eliminate the male surgeon as well as the male physician? Seriously speaking, science and skill produce results at the head of the operating table, just as they do everywhere else!

It is not only following the practices of the profession in all the other fields, but it is absolutely essential that a standard of scientific learning be exacted of the anesthetist, if the interest of the surgical patient be properly safeguarded. The time is long since past when "ether by the open drop method is good enough." Other methods and other anesthetics must be administered, not occasionally, but frequently, if the patient's interest is the supreme factor. The unknown response of the patient to the influence of the anesthetic precludes an exact determination in advance of the preferred anesthetic and method in each individual case, and a change is, therefore, frequently advisable or necessary during the operation. The anesthetist, who is incompetent to administer the standard anesthetics by the various approved methods, and adapt the depth of the anesthesia to the physical condition of the patient, or who does not possess a good knowledge of physiology and of the action and uses of the drugs and means ordinarily used in the work, is unworthy of the name specialist, and should not be considered a member of the properly equipped surgical team. If, of the Captain of the surgical team of the future an extra degree is to be exacted, thereby requiring, in a continually increasing number of instances, a total of three degrees, ought not this sub-member of his team be required to furnish just one? But if the view is approved that anesthetists "are born, not made," then let us at least keep a registry of their births, so that all may know who they are!

The physician, as well as the surgeon, is concerned in the anesthetic and the anesthetist, as this is a matter that ultimately ramifies the entire profession, and whenever the consensus of opinion of its members demands a standard, educational qualification for the anesthetist, it will be written in the organic law. May that day soon dawn!

NOTE.—After the foregoing was in type the case of Nations vs. Ludington, Wells & Van Schaick Lumber Co. was reported. Here the patient, a laborer, died from the effects of the anesthetic before the operation was begun. The Supreme (Appellate) Court of the State of Louisiana holds that employing a non-medical anesthetist, with no emergency existing, constituted negligence, and increased the damages awarded by the trial court to the plaintiff to $10,000. This Supreme Court was emphatic in its declaration that in the case adjudicated, one contemplating minor surgery only, a physician should have been employed to administer the anesthetic, although the officiating anesthetist was experienced in this line of work, and administered the anesthetic in the presence, and under the direction, of the surgeon.

BRETTON HALL, EIGHTY-SIXTH STREET AND BROADWAY.

## Medicolegal Notes.

**Accident Insurance Against Blood Poisoning—Sufficiency of Notice.**—Action was brought upon an accident insurance policy which insured a surgeon against loss of sight caused by blood poisoning during a professional operation. The uncontradicted testimony showed that the plaintiff contracted an infectious disease from a patient while delivering her in childbirth in October, 1909. He was subsequently treated and attended by experienced physicians and specialists down to April 4, 1911, when the disease resulted in the loss of sight of both of his eyes caused by blood poisoning from the wound suffered in the professional operation. All of the six medical experts who attended the plaintiff testified that the loss of his eyesight was a direct result of the syphilitic infection, by reason of the injury he had received in the professional operation; that there are different varieties of blood poisoning, and any of them will produce blindness if attacking the eye; and that syphilitic infection such as the plaintiff suffered from produces blindness. It was held that the plaintiff's claim was one provided for and his loss was insured against in the policy.

Notice was not given to the insurance company until March 14, 1911. Testimony was given by the medical experts that the kind of blood poisoning from which the plaintiff was suffering did not usually manifest itself for a long period, and might occur after one, two or three years. It was held that the plaintiff was not required to give notice, under the clause in the policy requiring notice to be given as soon as might be reasonably possible, until he learned that his sight was destroyed.—Maryland Casualty Co. of Baltimore v. Ohle, Maryland Court of Appeals, 87 ad. 763.

**Practising without Authority.**—On the prosecution of a person charged with violating the medical practice act on the ground that he does not possess an unrevoked valid certificate from the State board of medical examiners, the Oklahoma criminal court of appeals holds that the production at the trial and the introduction in evidence of such certificate is a complete defense to such charge. This rule, however, is not intended to, and does not, protect such person from prosecution if he aid and abets another to violate the medical practice act in so far as his connection with such other unauthorized person is concerned. A person who does not possess a valid, unrevoked certificate from the State board of examiners is held not entitled to practise medicine under the laws of the State, and is not authorized to render medical aid except in emergencies and such other cases as are specifically exempted by the statute. And this is true even though he worked with or under the directions of a duly authorized practitioner; and it is immaterial whether he works for a fee or percentage, or whether he is employed on a salary.—Gobin v. State, 131 Pac. 546.

## MEDICINE AND THE MONOPLANE: A LESSON IN THERAPEUTICS.

THE daring with which modern enterprise and inventive genius have conquered the seemingly insuperable difficulties of aerial flight is fully equaled by the zeal with which many apparently baffling problems of medicine have been attacked. This simile is suggested by the important case reported in the *Lancet*, January 31, 1914, by V. E. Negus, late House Surgeon to King's College Hospital, London. This case brings to a focus some of the ultra-modern methods of medicine and surgery, methods which are fully in keeping with the aggressiveness of science and human achievement. In further agreement with the above simile the case was one that resulted from an accident in aerial flight.

The patient was a young man nineteen years of age who had sustained a compound fracture of the left tibia and fibula, when his monoplane struck the ground after diving from a height of about 60 feet. The bones were at once wired together and the wound was partly stitched up. Three days later when the heroic aviator was admitted to the hospital the tissues about the wound were edematous and the discharges were offensive. Under anesthesia the stitches were removed, the wound was cleaned out and left open, and the leg was fixed in a box splint. The next day Sir Watson Cheyne removed the wires and fixed the bones by means of a Lane's plate, at the same time establishing thorough drainage.

Up to this point the case epitomizes the current attitude with respect to the treatment of compound fractures and the limitations and failures of the latest methods. But the patient was destined to summon other resources of modern medicine and surgery. The hospital staff had no easy problem on their hands. Their patient was not merely a case of infected compound fracture. In a few days he was a fully developed case of acute tetanus. On the eighth day after the accident the patient complained that he could not open his mouth well while taking his tea, and he had pain in the back, and a slight rise in temperature. The following day the symptoms of tetanus were pronounced and unmistakable. Chloral was administered in 20-grain doses every four hours. Tetanus antitoxin was injected subcutaneously, by lumbar puncture, and into the great sciatic nerve. Smears from the wound showed the presence of tetanus bacilli, and in view of the short incubation period and the prospect of further absorption from the wound, it was decided to amputate the leg. This was done under the intravenous method of anesthesia, 1½ drams of hedonal and 5 c.c. of ether being injected in 1½ pints of saline solution.

The further treatment of this patient illustrates the happy results that follow persistent therapeutic endeavor. The painful and spasmodic symptoms of tetanus continued unabated. Morphine and atropine and chloral in heroic doses were administered. At one time the patient was comatose from the large doses of chloral used; he was then given strychnine and inhalations of oxygen bubbling through absolute alcohol. For a general spasm with cessation of respiration he was given chloroform on a mask. Paraldehyde in doses of 12 c.c. was administered per rectum, and later was given intravenously in doses of 5 c.c. together with 5 c.c. of ether and 150 c.c. of saline solution. Potassium bromide, morphine, atropine, hedonal, and repeated doses of tetanus antitoxin were also used. On the tenth day following the first manifestations of tetanus the patient showed signs of improvement. During the course of this day he received as much as 10 drams of paraldehyde in addition to morphine, bromides, and chloroform inhalations. During the next twelve days the symptoms of tetanus gradually yielded to the persistent use of antispasmodics and the injection of the specific antitoxin, while the patient's strength was fortified with oxygen and champagne. A secondary operation on the stump was required two weeks later. The patient left the hospital, cured, eight weeks after the accident, drove about in his motor-car, and signified his intention of again braving the perils of the air.

This case is reported in detail because it illustrates in many ways the trend and successes of modern medicine and surgery. The one patient had experienced in the course of his eight weeks of illness the following up-to-date modes of treatment: Wiring of bones, Lane-plating, amputation for tetanus, intravenous anesthesia, antitoxin therapy by lumbar puncture and intravenously, and the intravenous injection of antispasmodics. The ultimate lesson which this case brings home is the need of therapeutic persistence and above all of therapeutic heroism in the presence of a dangerous and apparently hopeless situation.

## CHILDREN'S SERVICES IN MUNICIPAL GENERAL HOSPITALS.

BECAUSE of its applicability to similar conditions that exist in many cities both in this country and abroad, the Report on Children's Services in the Municipal General Hospitals in Manhattan and the Bronx, recently published by a Committee on Inquiry appointed in New York City, is of considerable importance. With a realization of the defects that exist in the facilities for the care of sick children, there can be no excuse for the proper authorities failing to provide adequate means for the removal of these defects. New York has made vast strides during the past few years in the improve-

ment of its public hospitals. Much remains to be done and it is creditable to the city that it perceives its own shortcomings and publishes these to the world.

It is first of all noted that the ratio of nurses to sick children is much smaller in the municipal hospitals than in the best private hospitals. Bellevue alone has a room in which the temperature can be forced to 95° so that premature infants can be suitably cared for. The detention rooms in all of the hospitals, with the exception of Bellevue, are inadequate. It is important that sick children entering a hospital should be isolated either in a small ward partitioned off into cubicles, or in separate rooms until there is no fear that these children will develop an infectious disease that may be transmitted to other children in the hospital. Cross infection is one of the greatest evils of children's wards and children's hospitals. It is a scandal to hospital administration that a child should contract in a hospital from another child a disease in addition to the one it already has. Vaginitis is the great opprobrium of children's wards, and its eradication requires separate baths for suspected children, the use of liquid soap, the use of gauze diapers which can be burned, the use of separate thermometers, and, above all, scrupulous cleanliness on the part of the nurse. The lack of suitable detention wards or rooms has resulted in hospital epidemics of infectious diseases, which have closed the wards for the reception of new cases until the end of quarantine.

It is pointed out that mothers will take their children long distances to a children's service in which they have confidence. For this reason the report recommends that the aim should be to centralize some of the children's services rather than to develop a complete service at each of the smaller hospitals. Bellevue is cited as an institution in which such a complete service has already been established. The smaller hospitals should be able to care for the general run of cases, but the case that requires special apparatus, facilities, or treatment should be sent to the centralized hospital. There should also be a children's hospital devoted largely to the care of "long term" cases, and of convalescent children.

In nearly all of the municipal hospitals surgical and medical cases are treated in the same ward. In one of the hospitals 77 per cent. of the acute surgical cases developed complications owing to faulty sanitary precautions. Children who are dying or who are in pain should be removed to a separate ward or room. Only too frequently does the sick or convalescent child hear the groans or watch the death agony of a child in a neighboring bed. Everything conducive to the peace and comfort of the little patient should be provided by a city which does not hesitate to spend its income lavishly in other directions. The safety and happiness of sick children demand adequate hospital equipment, including ample isolation and auxiliary rooms. There should be rooms for children recovering from an anesthetic, rooms for very sick and for dying children, and a special ward for convalescents.

## URIC ACID IN RELATION TO CHRONIC ARTHRITIS.

THERE is still a good deal of speculation regarding the actual status of uric acid in relation to chronic diseases of the joints. In gout the etiological rôle of uric acid has been clearly established. There are certain cases of atypical gout which resemble so closely other types of chronic multiple arthritis that a differential diagnosis between the two forms is next to impossible. For this reason considerable hope has been entertained that the quantitative determination of the uric acid in the blood and in the urine would enable one to differentiate between the two conditions. The following changes have been regarded as characteristic of gout: an endogenous uric acidemia, or the presence of uric acid in the blood even when the patient is living on a purin-free diet; a relatively low production of endogenous uric acid; and a delayed excretion of exogenous uric acid, whose production is also relatively diminished. These characteristics have been pointed out as a means of enabling one to classify properly the cases of chronic arthritis that lie on the borderland between gout and other conditions. The validity of this test has been subjected to careful scrutiny by M. Ljungdahl, who reports his results in the *Zeitschrift für klinische Medizin*, Vol. 79, Nos. 3 and 4. The observations were made on twelve cases of chronic polyarthritis, which were clinically of a non-gouty character. His conclusions are directly at variance with the views generally accepted.

Thus, it is pointed out that the peculiarities in uric acid excretion which are supposed to be characteristic of gout are not sufficiently marked to enable one to use these peculiarities as a differential criterion in the borderland cases. Moreover the low production of endogenous uric acid is found both in gouty and in non-gouty polyarthritis. The variations in the production of exogenous uric acid are so pronounced as to deprive this factor of any importance in the differential diagnosis. The rapidity of the excretion of uric acid is often greater in the non-gouty types of arthritis than in the gouty types, nevertheless this distinction is neither so regular nor so common as to be of any diagnostic value, when considered alone.

The investigations of Ljungdahl show that it is impossible to differentiate between the two types of arthritis by means of an estimation of the excretion of the endogenous and the exogenous uric acid.

## SUICIDE IN CHILDREN AND ADOLESCENTS.

THE self-inflicted death of an individual of tender years shocks the heart of humanity as one of the most pathetic and discordant notes of modern civilization. The suicide of a child or adolescent is as inexplicable as it is distressing. That an individual at the threshold of existence, when joy and hope impart the keenest zest to life, should seek self-slaughter, is a problem for the psychologist and social student to solve. Child suicide has shown a tendency to increase within recent years. The con-

centration of people in large cities, with all the evils of abject environment and of suggestion, may be assigned as a partial explanation of this increase. But the more immediate causes are an inherited psychic inferiority coupled with a faulty home and school training.

Professor A. Eulenburg of Berlin has studied this subject for many years, and in a small brochure* he now permits the results of a special analysis of the cases of child and adolescent suicide that have occurred in Prussia during years 1903, 1904, and 1905. During the last-mentioned year there were 603 suicides of individuals less than twenty years of age. Of these 403 were males and 200 were females. Under the age of fifteen there were 69 suicides, of which 57 were boys and 12 were girls. From the age of sixteen to the age of twenty there were 534 suicides of which 346 were males and 188 were females. From these figures it is observed that there are twice as many suicides among males under twenty as there are among females. This proportion is not merely true of any one year but occurs with such uniformity from year to year as to acquire the force of an underlying law. The excess of male suicides is still greater under the age of 15, when there are four times as many self-inflicted deaths among boys as among girls. After the age of puberty the number of girl suicides gradually increases, so that from sixteen to twenty the ratio of male to female suicides is as 2 is to 1.

Certain interesting facts are gleaned from a study of the immediate causes that are assigned for the particular instances of suicide in young people. In the female sex the most common cause is disappointment in love and associated factors, such as paternal opposition, seduction, etc. Fear of punishment is the next common cause of suicide in the girl. There are a great many other miscellaneous causes assigned for particular instances, as remorse, shame, incurable disease, etc. On the other hand, in young males the predominating impulse to suicide is the fear of punishment, chiefly for failures at school. This impulse is assigned in 40 per cent. of the cases of suicide in males under twenty. There is also a marked distinction in the mode of suicide adopted by young males and females. In the former shooting and hanging predominate, while in the latter poisoning and drowning are the most common modes of self-slaughter. Suicide pacts are particularly frequent in the young, the author's statistics showing no less than 66 instances.

The recital of these facts and figures is a grewsome commentary on the darker side of civilization. The subject is an unpleasant one in the extreme, nevertheless it cannot be ignored by physicians and sociologists. The remedy for child suicide is closely bound up with the prevention of psychic inferiority and of its transmission to the next generation; with the improvement of home conditions and of home training; and with the adoption of sane pedagogical methods which will eliminate some of the adverse stresses to which many children and adolescents are subjected.

*"Kinder- und Jugenselbstmorde, von Geh. Medizinalrat Professor Dr. A. Eulenburg, Berlin. Halle a. S.: Carl Marhold, 1914.

## LATENT AND MASKED DISEASES OF THE RENAL PELVIS.

THERE are many diseases in which the atypical and larval cases exceed in number the typical cases as set forth in the textbooks. According to T. Hausmann (*Zeitschrift für klinische Medizin*, Vol. 79, Nos. 3 and 4) the affections of the renal pelvis are to be included in the above group. In his experience a large proportion of the cases of disease of the upper urinary passages run an atypical, larval, or masked form, parading under the guise of other diseases, such as appendicitis, rheumatism, sciatica, neuralgia of the abdominal wall, intestinal catarrh, hysteria, etc. Disease of the renal pelvis is much more common than is generally believed, and occurs with especial frequency in women. The chief manifestation is urinary stasis resulting from nephroptosis with dilatation of the renal pelvis and subsequent pyelitis. Nephrolithiasis is less common.

In only some of the cases of pyelitis is the condition a suppurative one. Very often the urine is clear and contains only a few leucocytes, erythrocytes, or pathologically transformed epithelia, and is free from albumin. In nephrolithiasis red blood cells are often the only pathological finding in the sediment. But sometimes a few red blood cells in the sediment are the sole evidence of an albumin-free nephritis. A gelatinous sediment indicates an affection of the renal pelvis. Bacteriuria, which may even exist with a clear urine, is the objective evidence of an infection of the upper urinary tract.

Lumbar succussion pain and pain along the psoas muscle, particularly if unilateral, may arouse a suspicion of inflammation of the renal pelvis, a suspicion that may be confirmed by the urinary findings or by cystoscopy, or radiographic examination of the kidney or renal pelvis.

## TUBERCULOSIS FOLLOWING TYPHOID FEVER.

IN an article read before the Medical Association of the Greater City of New York, January 19, 1914 (*American Medicine*, January, 1914), Dr. Charles E. Woodruff makes the claim that tuberculosis follows typhoid fever far more frequently than has hitherto been suspected. Matson of Portland, Ore., who was the first to notice the phenomenon, and the only one who has searched for the facts, finds a record of typhoid fever in 17 per cent. of his cases. We have long known that typhoid fever is frequently followed by a chain of more or less serious sequelæ, but these new facts show that they are worse than we suspected.

The explanation is to the effect that many if not all adults harbor latent tuberculous foci, which serve the purpose of autovaccination to develop antibodies rendering them immune to virulent infection from without but not sufficiently so to drive out their own parasites. If anything happens to check this process of immunization, such as undernutrition, bodily or mental fatigue, exposure to wet, or a new infection, the latent lesions may take on activity

until we again develop antibodies to arrest the process, which a certain percentage of us fail to do. Hence it follows that where typhoid fever is prevalent so is tuberculosis, and that if we reduce typhoid fever by any means whatever tuberculosis automatically follows. This fact has been proved as to purifying water supplies.

The statistics presented seem to show that there is a definite ratio between typhoid fever and tuberculosis the world over. When the former is reduced to a minimum the other causes which activate latent tuberculosis keep the admission rate up to 1.5 to 2 per 1,000 in all armies except the Dutch and our own, for which exceptions the causes have not yet been found. When typhoid fever is reduced there is of course a coincident reduction of other intestinal infections, and a general improvement in all morbidity rates except in the senile diseases which are necessarily in greater ratio. Hence the reduction in tuberculosis is generally more than the reduction of typhoid fever alone would account for.

The facts presented seem destined to modify current ideas as to tuberculosis and the crusade against it, for it looks as though general sanitary measures have reduced the death rate far more than the specific measures directed against consumptives. Considerable interest has been aroused by the men who are quoted as saying that typhoid vaccine acts like tuberculin. These cases must be very mild and the immunity quickly restored unless some other factors like exposure to wet or fatigue prevent. The tuberculosis rate in the army has not changed materially since inoculations became compulsory, although it is still double what it ought to be. The cases should be studied to see what relation they bear to the inoculations.

## A NOVEL TELEPHONE SERVICE FOR PHYSICIANS.

THERE has been inaugurated in Paris a new form of telephone service which is of special value to physicians. In each central office there is an operator whose special duty it is to receive and record telephonic messages that are meant for those who subscribe to this particular form of service, and who may or may not be at home or at the office at the time that these messages are received. The subscriber, at his leisure or on his return to his home or office, calls up the special operator and is given the messages that may have been received during his absence or while he was otherwise kept busy. This mode of recording and transmitting messages has already been adopted in Norway and in Austria. In the latter country it has been in successful operation since 1912.

The advantages of this service are obvious. It enables the practitioner who may be compelled to leave his office in the absence of an attendant to keep in touch with his patients. This is no small boon to the young physician of limited finances. On the other hand, to the busy practitioner who does not wish to be interrupted by the frequent summons of the telephone during his office consultations, the service above described affords a distinct advantage, for he may arrange to have all of his calls and messages received by the special operator, so that he may at any time get these messages or calls in one batch. There can be little doubt that the adoption of this novel plan in the larger cities of this country would meet with immediate success. The loss of time which every practitioner suffers on account of being held up by many of his patients over the telephone either for advice, or, alas, for idle gossip, is not inconsiderable. Under the present system the physician or his attendant is practically at the mercy of everyone who chooses this means of gaining audience. The special operator who receives the physician's calls and transmits them to him at his convenience may become a potent means of checking the extent to which unnecessary and flippant demands on the physician's time have been practised.

## News of the Week.

**Operations on Tonsils.**—The Public Health, Hospital, and Budget Committee of the New York Academy of Medicine recently adopted the following resolutions:

"Resolved, That it is the sense of this Committee that all operations on the tonsils should be performed in hospitals or in such dispensaries as are provided with operating rooms and with recovery ward facilities.

"Resolved, That private hospitals of the city be requested to cooperate with the Health Department of the city in the operative care of children with enlarged tonsils and adenoids; that these hospitals provide proper and adequate facilities for such cases and that the city compensate the hospitals for this special service; and, further, that the public hospitals be requested to provide similar facilities, without special compensation."

**Alien Insane Bill Signed.**—Governor Glynn of New York on February 19 signed the Blauvelt bill which gives to the Governor the power to appoint a commission to endeavor to obtain Federal legislation which will relieve New York State from the support of the alien insane. The Governor at once appointed Senators Blauvelt and Brown and Dr. Spencer A. Dawes as members of the commission. They will go to Washington to urge the passage of a measure which will place upon the Federal Government the burden of caring for the insane who reach this State from foreign countries. It is estimated that the desired legislation would save the State about $3,000,000 a year.

**Ehrlich to Sue.**—It is reported in the German newspapers that Professor Ehrlich has decided to bring suit for criminal slander against a Berlin physician who recently made the assertion that the administration of salvarsan was so deadly that it might be prohibited in Germany by law, and that 275 deaths had occurred as a result of the use of salvarsan, besides numerous cases of blindness, deafness, lameness, etc. Professor Ehrlich replied that it was at present impossible to determine how many deaths had occurred from this cause, but that even 275 was an infinitesimal number when compared with the number of cases which had been treated. It is said that he will call upon the medical fraternities of Europe and of America to give evidence as to their experience in the use of the drug.

**Sale of Mercury Restricted.**—The Board of Health of New York City at a recent meeting passed in its final form a resolution restricting the sale of bichloride of mercury. The resolution, which will become effective on March 1, reads as follows: "No person shall sell or offer for sale at retail bichloride of mercury, otherwise known as corrosive sublimate, in the dry form except upon the prescription of a duly authorized registered physician or veterinary surgeon, and then only in tablets of a particularly distinctive form and color, labeled 'Poison' upon each tablet and dispensed in sealed glass containers conspicuously labeled with the word 'Poison' in red letters."

**New York's Ambulance Service.**—The Board of Ambulance Service of New York City has compiled statistics for the year 1913, which show that at the public hospitals the ambulance calls averaged 117 a day; that at the private hospitals they averaged 200 a day; and that the total during the year was 114,453. An average monthly compilation has also been made giving the different causes for which the ambulance was called; thus, the average number of cases of alcoholism for which ambulance calls were sent was 500 a month, the minimum for a month being 417, and the maximum 570. The lowest number of calls for persons with fractured skulls was 117, and the highest 148. Other figures are: Cerebral hemorrhage, lowest, 30; highest, 44; average, 36; bullet wounds, lowest, 53; highest, 82; average, 66; stab wounds, lowest, 61; highest, 97; average, 79. The average number of unnecessary calls per month was 175.

**Honor Panama Physicians.**—The medical fraternity of the Canal Zone gave a farewell dinner at the University Club, Panama, on February 22, in honor of Dr. William Deeks, chief of the medical clinic, and Dr. James Perry, chief quarantine officer, who will leave the service on April 1 for a trip around the world.

**Prize for Ehrlich.**—The Cameron Prize of the University of Edinburgh has been awarded to Professor Paul Ehrlich in recognition of his discovery of salvarsan and other contributions to medical science. The prize was established as a reward for highly important and valuable additions to practical therapeutics.

**Sea View Hospital.**—The Medical Board of the Sea View Hospital, Staten Island, gave a dinner at the Union League Club, New York, on February 20, in honor of Dr. Richard Kalish, Commissioner Kingsbury, and ex-Commissioner Drummond of the Department of Charities.

**Bertillon's Brain.**—The brain of Dr. Alphonse Bertillon, the creator of the system of criminal identification by means of exact measurements, has been found to weigh 1,525 grams, or 165 grams more than the average. This is the more remarkable as Dr. Bertillon had suffered from anemia for some time before his death, and the brain showed evidence of shrinkage.

**Women Internes Appointed.**—The Trustees of Bellevue and Allied Hospitals, New York, have voted to admit as internes Dr. Helen Palliser and Dr. Ana Tjohnlands, who, as reported last week, successfully passed the examinations. This is the first time that this institution has had women internes on its service.

**Causes of Infant Mortality.**—A systematic study of the causes of infant mortality in New York State, including a survey of the infant welfare service and a census of the infant population, will soon be begun by the New York State Department of Health. Commissioner Biggs plans to have the State undertake the instruction of mothers as to the proper care of infants and of themselves before and after the birth of the child, and in this way hopes to effect a reduction of the alarming death rate among babies in the State.

**Charitable Bequests.**—St. Luke's Hospital, New Bedford, Mass., receives a bequest of $50,000 by the will of the late Mrs. William Abbe of that city.

By the will of the late Mrs. Augusta Chapin of New York, St. Luke's Hospital, New York, receives $10,000; St. Mary's Hospital for Children, $3,000; St. Mark's Hospital, $5,000, and the College of Physicians and Surgeons, Columbia University, $1,000. A portrait of the testator's father, the late Dr. Thomas F. Cook, is bequeathed to the New York Academy of Medicine.

St. Luke's Hospital, Philadelphia, will receive $82,000 from the estate of Mr. Asa Packer, who died in that city in 1879, leaving his money in trust to his three children until their deaths, when it was to be divided among various institutions in which he was interested. His directions have been contested by his grandchildren, but the bequest to the hospital has been sustained.

**Low Infant Mortality.**—Montclair, N. J., claims a remarkably low death rate among infants under one year of age during 1913. A recent report of the city health department places the rate at 64 per 1,000 births, the previous low record of the town being 79 per 1,000. Between 1880 and 1894 the infant death rate in Montclair was 136 per 1,000 births; from 1895 to 1904, 130; 1905 to 1909, 96, and 1910 to 1913, 86.

**Nurses Graduate.**—The graduation exercises of the Mount Sinai Hospital Training School for Nurses were held at the hospital on February 17 and fifty graduates received diplomas from the president of the school.

**New Radium Field.**—A Canadian engineer has reported the discovery of a vein of carnotite in New Zealand. The ore will be mined and worked for radium.

**Vivisection Inquiry Requested.**—The Vivisection Investigation League of New York has recently been in communication with the District Attorney's office seeking to have an investigation made of complaints preferred by them against some institutions in this city. The District Attorney has declared that such investigations properly belong to the Department of Health, but that if any evidence of crime is submitted he will act promptly. An investigation on similar lines made a month ago by one of the assistant district attorneys disclosed no material for a Grand Jury.

**Louisville Hospital.**—The new City Hospital of Louisville, Ky., was formally presented to the city by the Board of Hospital Commissioners on February 7, and was accepted by the Mayor and the Board of Public Safety. The removal of 187 patients from the temporary hospital on Center street to the new building was accomplished on February 11. The new structure cost about $1,000,000.

**Washington Emergency Hospital.**—Plans for the construction of a new emergency hospital on New York avenue, between Seventeenth and Eighteenth streets, Washington, D. C., have been prepared, and the work of clearing the ground

has begun. The structure will be nine stories high, with a frontage of 125 and a depth of 130 feet. It will contain three operating rooms, up-to-date laboratories, *x*-ray rooms, and a roof garden.

**St. Vincent's Emergency Ward.**—The new emergency ward in St. Vincent's Hospital, New York, which has been equipped as a memorial to Dr. Francis Norman O'Loughlin, surgeon on the *Titanic*, who lost his life at the time that vessel sunk, was dedicated on February 16. The ward contains three rooms, one with nine beds for general usage, one with three beds for patients in delirium, and the third with five beds for an overflow or for women patients when necessary.

**Report of St. John's Guild.**—During the summer of 1913, according to the annual report of the president of St. John's Guild, 2,134 patients were admitted to the Seaside Hospital at New Dorp, Staten Island, for treatment. Of this number, 2,088 were discharged as cured or improved. There were only 21 deaths. The number of hospital days treatment was 23,827. The Floating Hospital of the Guild also did full duty. From June 30 to August 30, fifty-two trips were made, and a total of 57,887 persons were carried; of these 15,252 were women, 28,254 were children of about six years and under, and 14,381 were babies. The total number carried was 2,270 in excess of those carried in 1912.

**The East Side Homes.**—The New York Association for Improving the Condition of the Poor has recently made a report on the Home Hospital which it established in 1912 in the East River Homes, otherwise known as the Vanderbilt Model Tenements, for the treatment of tuberculosis. The experiment was carried out under the general direction of Dr. Linsly R. Williams. Twenty-seven families, seventy-nine members of which were tuberculous, were provided with sanitary homes, ample sunshine, fresh air, freedom from undue work and worry, skilful medical care, reasonable segregation, and constant nursing supervision. Eleven of these families, containing twenty-three tuberculous patients, twelve of whom were wage earners, were discharged during the year. Six of the eleven families had been rehabilitated physically, socially, and economically. The other five had to be dismissed because of persistent intemperance or refusal to follow advice; their condition, however, was improved. Of the 135 individuals treated in the hospital, fifty-four were consumptive and twenty-five were suspicious cases. The results obtained with the adult patients compared very favorably with those of the best sanatoria, one of the most marked results being that no new cases developed after admission. Of the adult patients, 61 per cent. were apparently cured, 22 per cent. were arrested, and 11 per cent. were much improved. In only four cases was there no progress. The improvement of the sixty-five children and sixteen infants was also most satisfactory. Economically and socially the experiment also proved successful, the average income of the six families discharged as "rehabilitated," having been increased from $6.42 to $15 a week. The actual cost of caring for tuberculous families in the Home Hospital was found to be less than that of caring for them in other institutions.

**Vital Statistics for 1913.**—The United States Census Bureau places the indicated national death rate for 1913, as estimated from returns in the "registration area," at 13.8 per 1,000. For 1912 the estimated rate was 13.6. Of the States in the registration area New York State led in the number of deaths, the rate being 15.2 per 1,000. Minnesota was apparently the healthiest State, the rate being only 10.7, while Wisconsin was a close second with a rate of 10.9. Of the cities in the registration area Memphis, Tenn., led with a death rate of 22.9, and Richmond, Va., was second with a rate of 22.4. Portland, Ore., showed the lowest rate, only 11 per 1,000, Minneapolis and St. Paul were second with 13, and Milwaukee was third with 14.2. Death rates per thousand for other cities were also announced, as follows: Los Angeles, 14.9; San Francisco, 16.7; Denver, 14.5; Chicago, 17.1; Indianapolis, 16.3; Baltimore, 19.4; Grand Rapids, Mich., 13.4; Kansas City, Mo., 16.3; St. Louis, Mo., 16.2; Omaha, Neb., 15.3; Newark, N. J., 15.7; Aubany, N. Y., 19.2; Buffalo, N. Y., 17.2; New York City, 16.2; Rochester, N. Y., 15.3; Syracuse, N. Y., 16.3; Cincinnati, 17.2.

**International Congress on Diseases of Occupation.**—The third International Congress on Occupational Diseases will be held in Vienna in September, 1914, and in this country a committee, of which Hon. William B. Wilson, Secretary of Labor, is chairman, Dr. George M. Kober, vice-chairman, and Dr. Alice Hamilton, Hull House, Chicago, secretary, has been formed for the purpose of inviting the attention of those interested. Membership fees, amounting to $5, may be sent by postal money order to the General Secretary of the Congress, Dr. Ludwig Teleky, No. 23 Türkenstrasse IX, Vienna, Austria. Among the topics to be considered are: The physiology and pathology of fatigue, with special reference to vocational work and to the effects of night work on the nervous system. Work in hot and damp air. Occupational anthrax. Pneumoconiosis. Injuries caused by electricity. Industrial poisons. Injuries of hearing caused by industrial pursuits.

**The Late Dr. Richard Van Santvoord.**—At a regular meeting of the Harlem Medical Association held on Wednesday evening, February 4, 1914, the following resolution on the death of their late president was adopted by the members of the society:

"The members of the Harlem Medical Association view with profound regret the death of one of its members and ex-presidents, Dr. Richard Van Santvoord. In his death we have lost an active and respected member, who was admired both as man and as physician.

"Resolved, That the Association spread upon its minutes this record and that a copy of this resolution be forwarded to his bereaved family.

Dr. John Remer,
Dr. John F. Connors,
Dr. William H. Luckett."

**The Late Dr. Turner.**—At a meeting of the Medical Board of the Norwegian Deaconesses' Home and Hospital held on February 4, 1914, the following resolutions were adopted:

"Whereas we have learned with regret of the death of Henry Cushman Turner, M.D., founder and dean of the Norwegian Deaconesses' Home and Hospital Staff,

"Resolved, That the Medical Board record the sentiment of its members, especially those who have worked with him in his hospital service, that a worthy, conscientious, painstaking, cultured physician has passed away. Be it further resolved, that a copy of these resolutions be sent to his

family, and the medical press, appear in the 'Yearly Report,' and be entered in the minutes.

Robert E. Coughlin, M.D.,
*Committee Chairman.*"

**Obituary Notes.**—Dr. James Joseph Burns of New York, a graduate of the University and Bellevue Hospital Medical College, New York, in 1902, and a member of the New York State and Broome County Medical Societies, the Physicians' Mutual Aid Society, and the Society of the Alumni of Bellevue Hospital, died at St. Francis Hospital on February 19 after a short illness from appendicitis, aged 33 years.

Dr. Charles E. Froelich, of Hartford, Conn., a graduate of the University of Copenhagen, Denmark, in 1870, died at his home on January 31, aged 69 years.

Dr. Garwood Harvey Attwood of Waterbury, Conn., a graduate of Yale University in 1840 and of the Medical Department in 1844, and said to have been in point of years the oldest, and in point of classes, the second oldest living graduate of Yale, died at his home from apoplexy, after a short illness, on February 1, aged 95 years.

Dr. William L. Wilson of Nashville, Tenn, a graduate of the Medical Department of the University of Pennsylvania, Philadelphia, in 1857, died at his home, on February 1, aged 80 years.

Dr. Robert C. Moon of Philadelphia, a graduate of the Jefferson Medical College, Philadelphia, in 1886, and long interested in the publication of books and charts from embossed type for the use of the blind, died at his home, from heart disease, after a long illness, on February 13, aged 70 years.

Dr. Lewis Y. Grubbs of Topeka, Kan., a graduate of the Medical College of Ohio, Cincinnati, in 1871, one of the organizers of the Jane C. Stormont Hospital, Topeka, and president of its surgical and medical staff since 1895, and a member of the American Medical Association and the Kansas and Shawnee County Medical Societies, died at his home on January 25, aged 75 years.

Dr. J. A. McCallum of Clinton, Ky., a graduate of the Bellevue Hospital Medical College, New York, in 1873, and a member of the American Medical Association and the Kentucky State and Hickman County Medical Associations, died suddenly in his office on January 26, aged 78 years.

Dr. Richard Gallego Crouch of Richmond, Va., a graduate of the University College of Medicine, Richmond, died at his home on January 27, aged 85 years.

Dr. James D. Fulton of New Orleans, La., a graduate of the Medical Department of the Tulane University of Louisiana, New Orleans, in 1902, and a member of the Louisiana State and Orleans Parish Medical Societies, died in the Truro Infirmary, after a brief illness on January 26, aged 42 years.

Dr. William H. Lincoln, of Wabasha, Minn., a graduate of the Rush Medical College, Chicago, in 1882, died at Mondovi, Wis., on January 25, aged 57 years.

Dr. James Edgar Banks of Prentiss, Miss., a graduate of the Medical Department of the Tulane University, La., in 1886, and a member of the Mississippi State and Jefferson Davis County Medical Societies, died at his home on January 28.

Dr. Roscoe C. Sprague of Liberty, N. Y., a graduate of the University of Louisville, Medical Department, in 1910, died in Louisville, Ky., from heart disease after a long illness on February 6, aged 27 years.

## Correspondence.

### HYPODERMIC INJECTIONS OF SALICYLATES IN RHEUMATISM.

To the Editor of the Medical Record:

Sir:—In the article on "Intravenous Injections of Sodium Salicylate," published by Dr. L. A. Conner in the last issue of the Medical Record, the following statement is made: "Attempts have been made to use it (sodium salicylate) by subcutaneous injection. This latter method has been found impracticable because of the painfulness of such injections, the local irritation, and the large quantity of solution required. A modification of the hypodermic method was introduced by Bouchard, who sought to obtain a local effect by the injection of a weak (3 per cent.) solution of the drug into the periarticular tissues of the inflamed joints. This method has had some vogue in France, but has gained no widespread popularity."

Since devising and publishing "the hypodermic method" of using salicylates dissolved in water or in oil (Medical Record, March 11, 1911), I have relieved my patients of their rheumatic infections, otherwise intractable. Many other physicians have had success with this plan of treatment, to my knowledge, and as yet no reports have appeared in medical literature condemning this method as "impracticable." As Dr. Conner has not reported the number and the histories of the cases in which he tried "the hypodermic method," and does not cite others who employed it without success, I challenge his dictum that it "has been found impracticable" as not based on fact.

That Mendel's method of injecting sodium salicylate intravenously, which was first mentioned in American literature in my article and which Dr. Conner has employed successfully in twelve cases (with 130 injections and occasional thrombosis at the site of puncture), has its advantages, there can be no doubt, but also that it can only be used by men specially killed in such work without serious danger to the patient, in hospital and private cases. Conscientiously I have never hesitated to order the most inexperienced assistant in my hospital service to give hypodermic injections of salicylates in severe chorea, rheumatic sciatica, and stubborn rheumatic arthritis, knowing that at the worst an occasional subcutaneous abscess might develop, on account of his imperfect asepsis, but I would not order him to give intravenous injections unless he were an expert and unless I knew that the solution to be absolutely sterile.

In severe chorea, usually maltreated for months by Fowler's solution before admittance to the hospital, four to six hypodermic injections of a 15 per cent. solution of salicylate of sodium (10 c.c. for every 100 pounds of body weight given every 24 hours) will quiet the patient so that appropriate doses of aspirin by mouth (15 grains twice daily for every 100 pounds of body weight) will practically cure the case in two weeks. In such cases the "intravenous" method of Mendel could only be used after anesthetizing the patient completely, while the pain caused by the "hypodermic method" can be reduced to a minimum by a previous hypodermic injection of cocaine, as detailed in my article mentioned above.

Another curious fact about Dr. Conner's publication is, that although he cites the articles of eight Germans and two Frenchmen, the name of his fel-

low townsman who devised "the hypodermic method" and the publication in which his article appeared are not mentioned at all.

NEW YORK. A. SEIBERT.

## OUR LONDON LETTER.

(From Our Regular Correspondent.)

LONDON AS A HEALTH RESORT—INFANTILISM—ROENTGEN SOCIETY AT LONDON HOSPITAL—VISCOUNT KNUTSFORD—OBITUARY.

LONDON, February 6, 1914.

LONDON is not named in lists of health resorts, but that it has some claim to the distinction has long been held by a few and last week the claim was boldly set forth at the Royal Society of Medicine (Section on Climatology) by Dr. S. D. Clippingdale. Of course, you know our death rate of 14.2 per 1,000 challenges comparison with all large cities. It has been described as the healthiest and, on the other hand, as the ugliest in the world, but that was prejudice or want of taste may be retorted. FitzStephen in the twelfth century was enraptured with its sanitary condition, due, he thought, to its good water supply. Sir Thos. Moore, three centuries later, made it the site of his Utopia. A libel was once current to the effect that a native London family did not survive beyond the third generation. To this Dr. Clippingdale replied that he himself was of the twelfth generation of a family living in London from Elizabeth's time, but he admitted that might be due to their healthy occupation, until recently, for his forebears mostly "found their bread on the living waters of the Thames." Elizabeth to prevent overcrowding ruled no new houses should be built within three miles of the city and only one family should occupy a house. Henry VIII, to stay infection, ordered a white wand to be put out from the window of every house infected. But Dr. Clippingdale attributed the healthiness of London to such natural advantages as situation, soil, open spaces. It received air, he said, straight from the North Pole, its site is on an inverted basin of clay, its acreage of open spaces (excluding royal parks and private squares) 5,000 compares favorably with the 540 of Paris and the 1,222 of Berlin. Its average rainfall 22 inches, but a set off to this is the great daily variations of temperature. Evelyn dedicated a treatise on the fog which prevented him and other loyal subjects seeing "your Majestie's handsome face." Dr. Clippingdale gives credit to gas fires for diminishing fogs but suggests they may not be so detrimental as supposed, the air being laden with carbon, an antiseptic, and carbonic acid had a soothing effect on the senses! There were enthusiasts who regarded the autumnal exodus as a modern fad, it being never necessary to leave London for health's sake. He admitted the absence of medicinal springs, those so reputed being closed, so we cannot set up as a balneological center. Possibly rheumatic patients may benefit from the well-drained soil. His grandfather living at Blackwall found his children when they had whooping cough were benefited by being sent to London. Bronchitis, asthma, and hayfever did well in London, as they do in other large towns. Still more, psychopathic and neuropathic cases were suited in London owing to its great size and many diversions. "Londonophilia" was seen in Johnson, Lamb, & Meredith. Some silly people, too, had done extraordinary things about it, as the wit who paved the front of his country house with cobbles to remind him by the rattle of traffic of the London streets. Then there was also "Londonophobia" which affected Heine, Grant, Ruskin, and many more. But there was no doubt it suited in many nervous cases, such as hypochondria, insomnia, neuralgia, drug habits, alcoholism, all cases requiring the opposite of the rest-cure. To treat such by hypnotic suggestion he considered degraded alike practitioner and patient. Submit such a patient to London's numerous diversions and send him for a tour around it. Set him to watch from the Tower Bridge the passing craft and think of the scene when Elizabeth's ships started to meet the Armada. Send him to study the customs and costumes of the East End. Let him visit the heart of the city and consider its historic associations and buildings. If a few days of London did the neurasthenic no good his case would be hopeless. In concluding his paper, the author quoted Horace Walpole, who said if he were a physician he would prescribe only 365 doses of London a year. "R. CCCLXV drach. Londin per an."

Infantilism was the subject of Professor Hastings Gilford's two Hunterian Lectures at the Royal College of Surgeons. He said many so-called dwarfs or midgets are not really the result of arrest but rather of protracted delay of development. The subjects of this retarded growth remain infants all their lives and when they grow old—they often do—their infantile characteristics persist, in spite of their wizened appearance. So extreme is their slowness in passing through the stage of childhood that in one case the lecturer found it took 20 years to grow as much as an average child grows in 5 years. This slow growth continues until over 30 years, when the little "man" may be no bigger than a 6 year old child. One of these "infantilates" passed as a child until nearly 30 and traveled on railways with half tickets. Another, a boy of 14, could pass as a baby in arms and, in fact, took the leading rôle in a theater, acting alternately as a baby and a diminutive man about town. The abnormal condition of these little people is called ateleiosis and "there are two kinds of ateleiotics" said the lecturer. One kind remain infantile always, so that their bones are grisly like those of children. In the other kind the bones harden but growth stops and the little beings are, as it were, stereotyped in the proportions and size of young children; they are mingled adults and children and often rejoice in beards and moustaches; some have actually become fathers or mothers of little creatures like themselves, *e.g.* the celebrated Tom Thumb married an ateleiotic lady who presented him with a daughter. They were on their traveling rounds at the time. Their baby, "Minnie Tom Thumb," died from inflammation of the brain in 1866.

In the second lecture, delivered on Wednesday, Professor Gilford advanced the theory that the fairies of folk lore were man's ancestors. He said the common notion that scientists believe we are descended from brutes like some apes of tropical forests was quite erroneous. There was, however, reason to believe that our ancestors were akin to the intelligent, lovable baby chimpanzees, orangs, or gorillas—much like human babies in appearance and disposition. Fossils had been found which throw much light on our ancestry. Skeletons of a big, coarse, brutish type were not necessarily those of our remote forefathers, but more likely off-shoots from a main stock. Other bones found belonged to the more elegantly formed, shorter people with big heads and features like those of modern children.

Such dwarfs had existed over large tracts of the earth and might represent the childhood of our race. Some had left pictures carved on rock or bone in many respects wonderfully like present-day children. Tradition, too, tells of pixies, fairies, elves, etc., simple, quaint, shrewd little people, active, good-natured, roguish, capricious, fond of dancing, music, and processions. In appearance, habits, and tastes they were always childish. In legends we heard also of giants, brutish, coarse, often cannibals, enemies of the little people—representing the brute-like fossil bones. The little people were spoken of as having died out ages ago, but the lecturer said there was reason to believe they lingered still in remote places and were the dwarfs in Central African forests or in deserts, islands, or mountainous regions of Asia or Africa. Their size, form, habits and general appearance were similar in many ways to the fairies of modern children's talk. The child of civilization, playing with bows and arrows, dancing, delighting in music, living animals, bird's nesting, bonfires, and dreading the dark, make one think of the children of the race whose small bones, pictures, and legendary records showed that the manhood of yesterday was the childhood of today. So the racial children, still living in the remote forests and places. Finally there is the modern show-dwarf, affected with "ateleiosis," not only a form of stereotyped childhood but an imperfect, rough copy of our ancestors as they lived upon earth 100,000 years ago.

The Roentgen Society met on the 3d inst. at the London Hospital where there is a department including *x*-ray and electrotherapeutic work. Dr. Scott gave a demonstration of the Wilson portable coil and showed some interesting *x*-ray plates. This apparatus is very light and so used in the wards for patients who are not fit to be taken to the *x*-ray rooms for examination. It makes use of a condenser before the current reaches the primary coil with the result that when the condenser discharges it delivers a high-frequency oscillating current of such a character that a secondary coil is not needed. Other points were stated, making the apparatus suitable for clinical work and it has been in use for some time in the hospital. *X*-ray photos were shown illustrating the application of steroscopic methods to medical purposes. They are made by taking them in pairs, the *x*-ray tube being placed a little more than an inch, first on one side, then on the other of the central line. On combining the pair it is possible to see the position and shape of a foreign body or a tumor, and it was said such photos were prepared in the department for the surgeons to see before operating. Another exhibit illustrated the use of *x*-rays for diagnosis. Collargol injection into the pelvis of the kidney had made it possible to discern the cause of suffering in some cases and the possibility of relief by operation. The first *x*-ray tube used at the London Hospital was shown. It was employed in 1896. The first photo taken with it showed a needle in the foot. Members of the society were shown the methods adopted to prevent the operator being ever exposed to the rays. Also to the mode of regulating dosage and to the filters employed in the application of the rays to deep-seated tissues.

Lord Knutsford, the former Colonial Secretary, who died on the 29th of January in his 89th year, was the eldest son of the late Sir Henry Holland, Physician to Queen Victoria and a leader of the profession, who was made a baronet in 1853 and died in 1873. Lord Knutsford is succeeded in the peerage by his son who has long had intimate relations with the profession as the Hon. Sydney Holland, chairman of the London Hospital for which he was so active in helping its finances as to have earned with some the title of "the greatest beggar in London."

Lt.-Col. O. T. Duke, M. B. of the Rifle Brigade, has died at the age of 70. He took his degree at the London University in 1867, entered the Indian Medical Service in 1869. In the Afghan War he was mentioned in dispatches and awarded the medal. Retiring in 1887 he was gazetted captain in the militia. In 1889 he was senior major in the Rifles and lieutenant-colonel in 1891.

Major E. D. F. Bringhurst, F. R. C. S. Ed., late of the army medical service, has died in his 60th year. He had studied in Paris and London as well as Edinburgh.

## OUR PARIS LETTER.

(From Our Regular Correspondent.)

ANNUAL PRIZES OF THE ACADEMY OF MEDICINE—EPIGASTRIC PUNCTURE IN THE TREATMENT OF FERICARDITIS—TREATMENT OF SYPHILIS OF THE NERVOUS SYSTEM—THE INTRASPINAL INJECTION OF NEOSALVARSAN—SUBDURAL CEREBRAL INJECTIONS OF THE SERUM OF SALVARSAN-TREATED ANIMALS—EMETINE IN AMEBIC DYSENTERY—OBITUARIES: HÉRARD, EMPIS—MONUMENT TO DIEULAFOY.

PARIS, February 1, 1914.

THE annual public meeting of the Academy of Medicine was held December 16, 1913. The order of the day was the announcement of the prizes for 1913. Among the winners was Georges Luys of Paris, who received the Ricord prize for his "Treatise on Gonorrhea." M. H. Vallée of Alfort received the Louis Boggio prize for his efforts in the prevention and cure of tuberculosis. M. Dopter of Val de Grace received the Adrien Buisson prize for his investigations in cerebrospinal meningitis.

Epigastric puncture in the treatment of pericarditis with effusion was the subject of a discourse before the Academy of Medicine by M. Marfan, who has employed this method with success since 1911. He pointed out the dangers of intercostal paracentesis, which dangers consist in injury to the internal mammary vessels, the pleura, and the heart. The technique of epigastric puncture is as follows: The patient is placed in a half reclining position on the bed, and a small trocar is inserted on the median line just below the xiphoid cartilage. The trocar is introduced obliquely in such manner as to glance over the posterior surface of the xiphoid cartilage. In this manner the pericardial sac is easily entered at the anterior position of its inferior surface, at a point where the effusion usually collects. Marfan has employed this method in 26 cases. There are only two contraindications: Excessive abdominal tympanites, and the funnel-shaped thorax.

The treatment of syphilis of the nervous system by means of the newer arsenical preparations has recently engaged considerable attention. This form of treatment has particularly been resorted to in tabes and general paralysis. Legendre and Juquelier reported at the Clinical Society of Mental Medicine, November 17, 1913, that they employed neosalvarsan by the intravenous method in doses varying from 0.15 to 1.50 grams. They had no untoward results, and obtained a certain degree of

improvement, particularly in one case of general paralysis. M. A. Marie in his service at Villejuif has observed similar results. Leredde similarly obtained good results. By beginning with very small doses, he found that one could attain doses as large as 1.5 centigrams of neosalvarsan for each kilo of body weight. The more recent the case the better are the results.

The intraspinal route has also been essayed. August Marie of Villejuif and Levaditi reported at the December meeting that they had instilled 1 to 6 centigrams of neosalvarsan dissolved in cerebrospinal fluid removed by lumbar puncture into the subarachnoid space. In 14 cases the above observers obtained 8 remissions. Paul Ravaut injects into the subarachnoid space one to four drops of a hypertonic solution of 0.60 gram of neosalvarsan in 10 c.c. of distilled water; the dose of neosalvarsan injected is 3 to 12 milligrams. These injections are well borne, and have given good results in two cases of secondary syphilitic nephritis, two cases of tabes, and one case of recent general paralysis. Jeanselme, Vernes, and Bloch inject by the spinal route a 1 to 1000 solution of neosalvarsan, of which they inject at first ¼ of a cubic centimeter, containing ¼ of a milligram of neosalvarsan. The injections are repeated every 8 days, and the doses are increased, without passing the limit of 5 milligrams. No accidents have been observed, and the serological changes have been favorable.

Finally, subdural cerebral injections have been resorted to. Levaditi, Martel and Marie have performed bilateral trephining in the parietal regions, and have injected about the frontal and parietal fissures 5 c.c. of the blood serum of animals into whom salvarsan has already been injected intravenously.

Chauffard was the first in France to use emetine hydrochloride in the treatment of abscess, amebic dysentery, and amebic abscess of the liver. He employed the technique of Rogers. M. Morestin reports an observation made by Leroy of Barres on a patient in whom an injection of emetine produced a rapid disappearance of amebæ from the stools. This, however, did not prevent the development of an abscess of the liver, which had to be opened but which healed rapidly. The fluid evacuated did not contain the thick and rosy pus characteristic of these cases, but a slightly turbid and slightly colored fluid which contained immobile amebæ.

Professor Hérard died recently at the age of 95 years. He was an honorary physician of the hospitals, a professor emeritus of the Paris faculty, a former president of the Academy of Medicine, of which he was also the dean. He became a Chevalier of the Legion of Honor at the early age of 35 years for his unselfish devotion during an epidemic of cholera in 1855. In 1865 he published in conjunction with Cornil a treatise on pulmonary tuberculosis. He was among the first to declare that tuberculosis is curable. He was a most zealous advocate of social measures in the campaign against tuberculosis.

Professor Empis died at the age of 89 years, a few days after Hérard. He also had been a president of the Academy of Medicine. Among his numerous writings may be mentioned his treatise on "Granulation," published in 1865. Since the appearance of this volume gray tuberculous granulation has been given the name "granulation of Empis."

On November 28 at the Hotel Dieu of Paris there was unveiled the monument to Dieulafoy, in the Amphitheater of Trousseau, where for 14 years he had attracted crowds of students from all parts of the world. Widal, Landouzy, and Mesureur delivered the eulogies. They referred to his matchless skill as a clinician, his love for work, and his eloquence and purity of diction.

## OUR LETTER FROM HAVANA.

(From Our Regular Correspondent.)

ABANDONMENT OF THE REGISTRATION OF PROSTITUTES —SMALLPOX ON THE "OHIO"—ANTITYPHOID VACCINATION—ASEXUALIZATION OF CRIMINALS AND THE INSANE—MEDICAL MATTERS BEFORE CONGRESS —PERSONAL.

HAVANA, January 4, 1914.

THE presidential resolution annulling the long established "Zone of Tolerance," went into effect on December 30. For the past 200 years a large part of Havana's prostitutes have been confined to a limited section of the city. In that quarter, designed as the "zone of tolerance," all criminal industries associated with and depending upon prostitution thrived and vice and the trade of the procurer flourished. The "business of prostitution" was a well regulated affair, and the women were registered and a license was given to them, while frequent medical examinations were made. But as the unlicensed or clandestine prostitutes were ten times more numerous than those with license and registration, and as the special department created in order to control prostitution was, with the exception of its medical officers, an organization that thrived upon what they could force from all Havana prostitutes, licensed and unlicensed, the Government decided to suppress official regulation. Therefore there will be no more licenses or registration and the "red light district" has been abolished, its inmates having migrated to all sections of the city; they will now have the regular police force to contend with.

Some apprehension has arisen in the eastern part of the island with the coming of the U.S.S. *Ohio*, with more than twenty-five cases of smallpox on board. The battleship is at present at quarantine at the Guantanamo Coaling Station and no cases have appeared on shore. Vigorous and extensive vaccination is being practiced in all places on the north coast of Oriente Province and there is every reason to believe that the outbreak will be limited to the *Ohio*.

Antityphoid vaccination of all members of the Cuban Army and Navy will soon begin. This work was started by Dr. Ferrer, an army surgeon, about three years ago, he having vaccinated about 3,500 men. Ten thousand remaining men will now be immunized. The procedure will probably be extended to the employees of all our large hospitals.

Asexualization or sterilization of habitual criminals is likely to be established in Cuba, a bill to that effect having just been introduced into the House of Representatives by Dr. Francisco M. Fernandez. The bill provides for the sterilization of habitual criminals, of persons suffering from chronic hereditary insanity, and of all rapists. A big cry has been raised on that account, sentimentalism trying to oppose the passage of the bill.

Other matters pertaining to medicine are being discussed in the Congress; funds providing for the celebration of the next Cuban National Medical Congress will soon be granted by the House, and a bill reorganizing the School of Medicine was re-

cently read by another medical man who is also a Congressman, Dr. Andres García of Santiago; he wants to abolish the long-standing custom of one professor having two or three different things to teach, and of course getting an extra salary for each.

Dr. Felix de Vera, a physician of long standing and good reputation, died at his home in Matanzas, on January 2, from angina pectoris.

A large number of Havana physicians attended a dinner given to Dr. R. Gutierrez Lee to celebrate his appointment as Minister from the Republic of Colombia, his native land, to our country. Dr. Gutierrez Lee has practised in Cuba for over thirty years and is well beloved by all his colleagues.

4. Leprosy: The Pulse as a Possible Indicator of the Progress of the Disease. (A Preliminary Note.) J. A. Honeij.
5. Ileal Stasis. H. W. Baker and D. V. Baker.

**1. Gastric and Duodenal Ulcers.**—C. Graham points out the typical diagnostic symptoms of peptic ulcer as follows: (1) The periodicity of the attacks and the perfect intermission or marked remission of attacks; (2) the almost exact similarity of symptoms occurring for days during the period; (3) the marked relation of symptoms to food intake (one-half to four hours); (4) the control of the symptoms by food, alkalies, lavage, posture, and rest. The types of cases in which it is particularly difficult to reach a correct diagnosis, or in which it is quite impossible to differentate from other lesions causing gastric symptoms may be divided into four groups: Group 1—This group comprises those patients with ulcers who give the classical symptoms of gallstones, and in whom no other gastric symptom can be elicited. Group 2—In this group may be found patients in whom the ulcer must have been latent for weeks or months, and whose first manifest symptoms were those of chronic ulcer with complications (hemorrhage, perforation, etc.). The symptom-complex in these cases is irregular and quite excludes the pathognomonic picture of ulcer. Group 3—In these cases the present chronic symptoms are very severe. The early symptoms were so mild that they may have been quite forgotten or overlooked by the patient. The patients will not allude to the early trouble unless carefully questioned, because nothing is of so much importance to them as the present, or recent years of distressing pain. Group 4—In the fourth group are those patients whose symptoms are of a more or less malignant type —marked loss of flesh and strength, pain or distress quite continuous, gas rather annoying, and vomiting of large amounts at irregular periods.

**2. Certain Phases of the Psychoneuroses.**—G. L. Walton states that it would be desirable in the subclassification of "neurasthenia," "psychasthenia," or "psychoneurosis" (preferably the latter) more freely to use the terms "brain fag" and "obsessive psychosis," and to recognize the fundamental difference between them. While the sufferer from obsessive psychosis may drift into chronic hypochondria, or into manic depressive insanity, he will become a case of dementia præcox only if he has the inherent brain defect which limits development and predisposes to deterioration. Prognostic injustice may easily be done by making the diagnosis dementia præcox on the basis of a single psychopathological outbreak with symptoms suggesting that disease.

**4. The Pulse Rate in Leprosy.**—J. A. Honeij notes that in all febrile diseases and especially in tuberculosis, there is an evening rise in temperature, pulse rate, and respiration. In leprosy this usual condition is reversed, so far as the pulse rate is concerned. In the morning the pulse rate is higher than at evening; often markedly so. That this condition is not due to the greater morning activity of the patient or to atmospheric changes has already been determined.

7. Magnesium Sulphate and Glycerine in the Treatment of Infections. E. M. Freese.
8. Two Remarkable Cases of Obesity. J. Weiss.
9. The Technique of Outlining the Thyroid Gland. M. S. Woodbury.

**1. Serial Roentgenography in Gastric Cancer.**—L. G. Cole has made a negative or positive diagnosis of gastric cancer in each of the 616 cases examined by means of serial roentgenography, and in not a single case (to the author's knowledge), in which he had made a negative diagnosis of gastric cancer or indurated gastric ulcer, has surgery or autopsy proved the existence of such lesion, nor has surgery or autopsy failed to reveal a definite organic lesion, requiring surgical procedure, in any case, where a positive diagnosis of carcinoma or indurated ulcer had been made. Six hundred and sixteen cases have been examined by serial roentgenography. Ninety-seven cases have been operated upon. In ninety-four of the cases the roentgenological diagnosis was proved absolutely correct. In three cases the surgical findings were more or less at variance with the roentgenological findings. Gastric cancer at any stage of development or indurated gastric ulcer may be detected by the use of serial roentgenography with as great a degree of accuracy as renal calculi or bone fractures may be detected by plain roentgenography. The time has come when a surgeon has no more right to operate on a chronic gastroduodenal lesion without a thorough roentgenological examination than he has to operate for a kidney stone or to treat a fracture without an *x*-ray examination.

**2. Intestinal Resection.**—By R. C. Turck. (See MEDICAL RECORD, February 21, 1914, page 364.)

**5. Sensitized Vaccines.**—F. E. Stewart enumerates the advantages following the use of Besredka's sensitized vaccines: (1) They produce but slight local reaction (inflammation at site of injection). (2) They cause no general reaction (malaise, increased temperature, etc.). (3) They may be given in much larger doses and much more frequently than the unsensitized bacterins (every twenty-four hours). (4) The immunizing effect is almost immediate (manifesting itself within from twenty-four to forty-eight hours). (5) They sometimes give successful results in very late stages of a disease, when no response is secured from the ordinary bacterins and even serum treatment is ineffective.

**6. Emetine in Amebic Dysentery.**—By F. G. Yeomans. (See MEDICAL RECORD, February 14, 1914, p. 315.)

**7. Magnesium Sulphate and Glycerine in the Treatment of Infections.**—E. M. Freese has obtained excellent results in the treatment of infections such as cellulitis, lymphangitis, etc., by means of external applications

of equal parts of glycerine and a saturated solution of magnesium sulphate. The latter has for a long time been used in sprains and inflammations to allay pain and abate swelling, and glycerine has likewise been used in the treatment of pelvic inflammations.

**1. Emetine Treatment of Amebic Dysentery.**—E. B. Vedder finds that emetine is a true specific in amebic dysentery and hepatitis, and the results obtained by its use compare very favorably with the results obtained with salvarsan in syphilis. The hypodermic use of the hydrochloride salt is the preferred method of treatment. A large percentage of the cases so treated continue to harbor *Entameba histolytica* (often in the encysted and most dangerous form) in the feces for some time. While in view of this fact it is impossible to state at present that patients treated by emetine will remain permanently cured, yet the prospects of obtaining permanent cures by this method are encouraging. The presence of a considerable number of these chronic ameba carriers constitute a sanitary menace to the community. It is possible that the amebas may be removed from these carriers by a course of irrigations of quinine or silver nitrate. Experiments have failed to show that emetine possesses any marked therapeutic virtue in bacillary dysentery, syphilis, rabies, or trypanosomiasis.

**2. The Functional Metrorrhagias.**—By A. Sturmdorf. (See MEDICAL RECORD, February 14, 1914, page 317.)

**5. The Precipitation of Colloidal Gold.**—D. M. Kaplan and J. E. McClelland describe the results they have obtained in the examination of the cerebrospinal fluid with the aid of the goldsol or gold chloride precipitation test which was first worked out by Carl Lange. The latter says that in order to ascertain the exact nature of the globulin in the cerebrospinal fluid he has made use of the most delicate known method in the field of protein analysis, namely, the determination of the gold number (*Goldzahl*) according to the method worked out by Zsigmondy. In Lange's article it is apparent that the sole purpose of the investigation was to determine the chemical nature of the substance in the cerebrospinal fluid commonly spoken of as globulin, and obtained *in vitro* by Nonne's half saturation with ammonium sulphate solution and known as "Phase 1" reaction. This substance has been subjected to the large number of reactions usually employed in the analysis of proteins, as well as to the determination of the gold number. The results obtained with the latter method, with fluids from patients with syphilitic diseases of the nervous system, suggested to Lange the possibility of using it as a specific test for syphilis of the nervous system. The technique, according to Lange, depends chiefly on the proper preparation of the reagent. He describes a color-scale to correspond with varying degrees of gold precipitation; this scale reads from a clear watery white, which is obtained with complete precipitation, through the partial precipitations giving, respectively, white-blue, light-blue, dark-blue, violet, blue-red and red-blue, to the original red of the indicator. Besides these color changes Lange considers as important the dilution in which the precipitation takes place. In his experiments the dilutions varied from 1 : 10 to 1 : 40,000. The authors have been unable to corroborate fully the results obtained by the other workers who have asserted that this reaction can be obtained in all cases of syphilitic disease of the nervous system. The most marked reactions and typical curves are obtained only in cases of general paralysis and taboparesis. A positive reaction occurs in most cases of cerebrospinal syphilis, but the curve is not characteristic. In the majority of the cases of tabes either no reaction occurs or only a weak reaction in the 1 : 10, 1 : 20 or 1 : 40 tube.

**7. Etiology of Hodgkin's Disease.**—C. H. Bunting and J. L. Yates in a preliminary note recently published, have reported that by repeated injection of the diphtheroid organism cultivated by them from cases of Hodgkin's disease, there had been produced in monkeys lesions of the lymph-nodes showing all the essential features of early Hodgkin's disease in man. Up to that time they had been unable to demonstrate that the organism could survive in the monkey for any great length of time, and therefore they felt that they could not assert that they had produced Hodgkin's disease in the monkey, or that they had even demonstrated any great pathogenicity of the diphtheroid organism for that species. Since making that report, however, the course of their experimental work has demonstrated fully the pathogenicity of the culture they were using, and has further shown that the virulence of the organism to the monkey may easily be increased even to the point of producing death of the animal after a relatively acute illness. While the histological picture of the enlarged lymph-nodes of the monkey taken three months after the successful inoculation leaves no question as to the relation of the lesion to that of human Hodgkin's disease of the same duration, the great difficulty seems to be to secure infection and at the same time to avoid so great virulence as to produce extensive necrosis and softening and even suppuration. The working space between these two limits seems very narrow. Extensive necrosis and leucocytic infiltration of the glands may seem foreign to the usual chronic picture of the lymph-nodes in Hodgkin's disease, yet a recent clinical case has demonstrated that even in man the virulence of the organism may be such as to lead to these features. Thus, since the author's experiments demonstrate that the diphtheroid organism is pathogenic for the monkey, that it produces a progressive enlargement of the lymph-nodes, with lesions similar to those of Hodgkin's disease in man, and further that the blood-changes in the monkey are similar to those in man, they feel fully assured of the etiological relationship of the diphtheroid organism (*Bacterium hodgkini*) in the production of Hodgkin's disease in the human being.

**1. Tuberculosis as an Infective Disease.**—W. Cecil Bosanquet concludes from his observations that infection with tuberculosis is very widespread and takes place largely in infancy and early childhood. It is partly due to bacilli derived from human sources, partly of bovine origin, but the former type greatly predominates. Direct communication from one human patient to a healthy individual does not occur in adult life under good sanitary conditions, with the possible exception of a few instances in which there has been very close and prolonged contact. Under bad hygienic conditions direct infection may occur, children being specially susceptible. The exact mode of transmission of the bacillus is unknown, but that inhalation affords the simplest explanation, although the localization of the chronic form of the disease in the lungs is not in itself evidence of direct implantation there. The chronic form of the disease met with in adults is due to their increased resistance, as compared with children who suffer from the acute variety of tuberculosis, and this increased resistance may be the result of early inoculation with sublethal doses of the bacilli. The outbreak of tuberculosis in later life may be due either to reinfection from without or to recrudescence of a latent focus of old infection. A general rise in resistance has been brought about owing to the wide dissemination of the disease among European nations, and the fall in the death rate is largely due to this factor and to improved hygienic conditions. From these conclusions one may further deduce the practical moral that the most hopeful measures which can be taken with a view of combating the disease are such as are directed toward improving the general well-being, and especially the housing conditions, of the poorer classes.

**6. Acute Tetanus with Recovery.**—By V. E. Negus. (See MEDICAL RECORD, page 391.)

---

### Münchener medizinische Wochenschrift.

*January* 20 *and* 27, 1914.

**Radiotherapy in Gynecology.**—Henkel's summary is as follows: (1) *X*-rays are contraindicated in sudden, life threatening hemorrhages; whenever the site and size of a tumor cause pressure symptoms; in strongly bleeding polypi; in malignant and other degenerations; in myoma in young subjects, and finally in cases in which diagnosis is not absolutely clear; (2) the rays are to be used with great caution when in the midst of treatment complications arise, such as fever, bowel disturbance, etc.; (3) at present the rays are best suited to the treatment of climacteric and other surely benign hemorrhages in elderly women. A microscopic examination of the endometrium should first be made. A certain number of myomata are also eligible to *x*-ray treatment.

**Combined Treatment of Carcinoma.**—Klein refers to the combination of mesothorium, *x*-rays and intravenous injections. He has now treated thirty-nine cancers in this fashion, all strictly inoperable, during four months past; so that he refers to his results as primary. The large majority of these were gynecological cases. When the knife was used, the same combined treatment was used afterward as prophylactic. The small quantity of mesothorium available makes the question of overdosage out of the question. The *x*-rays, however, may be readily overdosed. By the intravenous route a formula by Merck comprising radium, barium, and selenium was used, with other substances, one apparently of secret composition. The technique for such treatment is naturally very elaborate. While much was learned the author admits that no chance is furnished for comparison with older methods. One starts out with no idea of curing all cancers, like the surgeon with the knife. Metastases, together with a certain degree of local extension, render cure impossible. Much is being done to stay the growth of inoperable cancers and radiotherapy is still in its infancy. There is also much difficulty and risk to be overcome. One important claim (of Döderleins) the author thoroughly endorses, to wit: that an operable carcinoma of the cervix may be cured with rays alone, in the absence of the knife. It will take four or five years to decide this possibility, for men will not feel quite justified in abandoning the chance of a knife cure. The prognosis in regard to cancer uteri has, is, in fact, showing notable improvement at present.

**Cause of Acute Anterior Poliomyelitis.**—Lust and Rosenberg have studied this subject very extensively upon fowls and conclude that fowls are not sensitive to the virus of this affection as found in men and apes, whether exposure is natural or artificial. The occasional occurrence of a paralyzed chicken in the neighborhood of an epidemic of acute poliomyelitis is not sufficient to identify the disease in fowls with that in man, so that anatomical and histological studies must be made in the diseased fowl. The latter have revealed various abnormal conditions in the fowl's spinal cord, as might have been expected; but acute poliomyelitis as seen in man and apes is not included. Nevertheless, but a few chickens have thus far been examined in this respect. But even if the histological finds are ever found to be the same, the failure of the virus to take still will furnish an obstacle to identity. Fowl paralysis is not the only disease of fowls which attacks the nervous centers. In fact, if we take the domestic animals as a class, centers are involved in a number of severe affections—Borna's disease in horses, the dog plague and rabies canina, guinea pig paralysis, and perhaps the fowl pestilence—are all evidently due to an ultrafiltrable virus, and all prevail in the form of epidemic diseases, just as does acute poliomyelitis in man.

**Is Diabetes Due Simply to a Primary Overproduction of Sugar?**—Rolly and David after some citations from the labors of predecessors along these lines give some results of their own. In regard to acidosis the authors find the maximum increase of the respiratory quotient several hours after injection of monosodium phosphate, etc. Porges, who sought chiefly to determine the period at which acidosis develops after intravenous injection of acids did not consider the respiratory quotient. Some of Porges' and the authors' experiments were made after elimination of the liver, this condition also tending to raise the respiratory quotient. If, however, strychnine convulsions are induced, with resulting increase of respiration, the injection of acids does not affect this quotient. The authors' final conclusion is that in human diabetes the rationale is an imperfect utilization of carbohydrates rather than an overproduction. Nothing advanced by other experimenters can controvert this view. This, however, applies only to recent diabetes, for a confirmed diabetic in addition to his non-utilization of sugar, also produces sugar which it cannot decompose.

**Retroduodenal Versus Transduodenal Choledochotomy.**

—Von Fink having performed three operations of each sort, seeks to draw conclusions as to relative indications, merit, etc. He seems but little versed in the literature of the subject, or at least cites but few authorities, and they old. His conclusions are that the retroduodenal method is indicated only when all inflammatory symptoms have run their course. The transduodenal method, on the contrary, is indicated in all cases in which any degree of inflammation is present of the choledochus, pancreas, etc. In routine the author first tests as to the practicability of the retroduodenal route in accordance with the above maxims. We must next determine whether the stone can be removed by the other method without injury. In two of the transduodenal cases of the author, the stone was expressed without the necessity of incising the fold, while in the third the latter step was required, and readily and safely effected. In connection with the retroduodenal method, it is often possible to mobilize a concrement and eventually, if thought best, remove it by the transduodenal route.

**Benzine Poisoning.**—Jaffé describes cases in man and animals, including experiments. Cases in man are becoming more frequent. Death seldom results. The symptoms pertain to the central nervous and respiratory systems. Aside from workers in benzine, cases not infrequently occur in children, from carelessness. The toxic dose is hard to fix, since in certain cases a mere swallow has caused death, while individuals have swallowed 50 c.c. without feeling the least discomfort. One of the author's cases in a strong male child, age 21 months, ended fatally after a sip of benzine. The symptoms were cyanosis, collapse, and vomiting of bloody mucus. Autopsy showed hemorrhages in both lungs and left pleural cavity. The child was a thymico lymphatic. Hemorrhages of the lung are in fact characteristic of benzine poisoning. This is accounted for by the action of the drug, however administered, on the vasomotor center. Benzine can also injure the pulmonary mucosa if directly aspirated. When inhaled it is also exhaled by the lungs. When this occurs *en masse* pulmonary hemorrhages occur. But when it is absorbed into the blood from the stomach alone, this absorption being gradual, a pneumonia may result (animal experiment). Benzine poisoning in the typical case, especially in children, appears to be due both to inhalation and ingestion, and the former may preponderate.

## Deutsche medizinische Wochenschrift.

*January 22, 1914.*

**Conduct to Pursue in Acute, Threatening Diseases of the Cord and Medulla.**—Grober, who has long been writing a series of articles on emergency treatment of acute diseases, sums up one of these very briefly, as follows: in all acute affections of the cord, unaccompanied by special indications—such as artificial respiration in Landry's paralysis, sluicing in again in caisson disease, exercising the swallowing muscles in bulbar paralysis, etc., etc.—the treatment should include rest, proper position, removal of all difficulties, prevention of complications, along with the best of nursing and diet. Of medical treatment there is hardly anything to be said save removal of subjective symptoms.

**Action of Papaverin.**—Pal, so well known for his studies of the smaller blood vessels, claims to have found in this long-known substance new properties, and speaks of it as a recent addition to our resources in certain directions. He finds its action identical with that of "narcotin." The new virtues claimed are the ability to oppose the contraction of the smooth musculature, not only of the arteries, but also of the intestine. It is superior by far to amyl nitrate for relaxing the tension of blood vessels, is useful in hemoptysis, has neither a narcotic nor constipating action, and is a local anesthetic. It is almost nontoxic. Many toxic bodies possess activities similar to those of papaverin and "narcotin"; but their toxicity is marked. The name "narcotin" seems to have been a misnomer.

**Bromide Treatment of Neurasthenia, Especially of Nervous Insomnia.**—Bodenstein does not refer to the fact that Beard, who first described neurasthenia, recommended a "home treatment" with bromide as better than no treatment at all. Large doses were recommended, enough to keep the patient in bed during some three-quarters of the day. Bodenstein writes from another viewpoint, recommending a synthetic (?) proprietary, containing sodium bromide, in cachets. This synthetic or mixture was devised for the treatment of epilepsy and contains no other active specific. He has thus far treated sixty cases of neurasthenia which comprise nervous irritability, gastric and cardiac neuroses, and insomnia. Some of his patients were arteriosclerotics. There is no claim made as to cure. The distressing symptoms are said to vanish promptly. In certain cases the treatment is carried out for months, and the nutrition improves in proportion, naturally indirectly, as the consequence of improved sleep and digestion. Each dose contains a gram of sodium bromate, and that it may be taken safely over months, the patients do not receive over two tablets daily.

**Thermotherapy of Gonorrhea.**—According to Bromberg, the knowledge that the gonococcus begins to feel a degree of heat above 40° C. has naturally led to attempts at its distinction by heat as high as 55° C. The early efforts doubtless failed, but recently have been revived in connection with scattering reports of cures. Aside from the simple measure of heating an ordinary sound and introducing it in both acute and chronic gonorrhea, others are claiming good results from diathermy. Several Germans report good results from electrically heating sounds placed *in situ*. These widely different forms of cure have not, of course, been analyzed and standardized. The result of all methods must be to submit the urethra to a heat of from 45° C. upward, the lower the temperature the more prolonged the exposure. The author used an electrically heated sound, and to render this tolerable cold was momentarily substituted for heat. The maximum high temperature used was 52°, the latter alone for fifteen minutes. Since in theory some six hours are necessary to kill the gonococcus, and no one refers to any such exposure, the treatment can only be regarded as an approximation. The initial temperature is 38°. increased not too rapidly to 52° C.

**Case of Osteogenesis Imperfecta, Illustrating High Fever after a Fracture in Which the Fragments Were Not Displaced.**—F. J. Poynton reports the case of a girl aged eleven years who was admitted to University College Hospital suffering from fractured left tibia and fibula. The girl had been admitted three times to this hospital and many times to the Great Ormond Street Hospital suffering from fractures of the legs. It took a very slight blow to break them, and this time the fracture was caused by a blow from the fist of a child. Her bones had been soft and easily broken from birth, and she had never been able to walk alone. The case is reported to illustrate the fever that may occur with the occurrence of a fracture not sufficient to disturb the fragments. In this case the temperature rose to 103° F. and kept up, with general malaise, for nearly a week.—*Proceedings of the Royal Society of Medicine.*

## Insurance Medicine.

**The Insurability of Women as Shown by Industrial Insurance.**—Louis I. Dublin, Statistician Metropolitan Life Insurance Company, New York City, presented the following ideas on this subject before the Medical Section, American Life Convention, August, 1913. Taken as a whole, insured women have been a source of considerable loss to the large number of companies doing business among them on the ordinary plan. The conditions influencing this loss he divides into three: First, is the difficulty of making a satisfactory medical examination of female applicants. The vital organs, such as lungs and heart, the condition of which determine insurability, cannot be as thoroughly examined, and few examiners insist upon the requirement that the chest be completely bared. As a result, some heart and lung conditions escape scrutiny and the applicants are passed as first-class risks. Also, at the present time, pelvic examinations are rarely made, thus allowing serious conditions peculiar to women to be passed unrecognized. Second, is a peculiar psychic constitution of women which manifests itself in an intuitive premonition of impending disease. This same instinct expresses itself in other forms, such as the misstatement of age, the concealment of important facts pertinent to the medical examination and even in the giving of evasive answers to the examiner. Third, is the element of speculation that enters into the insurance of women. The consideration of insurable interest is often lacking. Until recently women were not important factors economically, and such insurances as were written were not effected by actual canvass, but were rather the result of the request of the parties concerned—husband or children. These individuals realize the physical condition of the insured and risk a few years of premium paying on the chances of receiving the larger benefits of the insurance. That this factor is the most important of the three is generally conceded. For these reasons the attitude of the companies toward the problem of insuring women has been a simple one. Restrictions in some form have been placed upon the business. Women have not been insured at all, or limited to what seemed to be desirable applicants to certain plans only and at extra premiums.

The results, until recently, have been far from satisfactory and the business as a whole did not come up to the standard. The experience of the few companies whose results were favorable has a special significance here. Of these are the New York Life and the Metropolitan Life, in both of which it was early anticipated that the mortality conditions among women generally noted were due largely to speculation. Their method to overcome this difficulty consisted in eliminating most of the harsh restrictions formerly imposed and in making increased active efforts to get a fair representation of female risks. Both companies insure women at the same rates and on the same conditions as men, provided that there be an absolute insurable interest shown in every case. Thus, the Metropolitan welcomes for insurance and actively canvasses women who are economic producers; those who follow a profession or a business of their own, or those enjoying an income of their own which would, at their death, involve a financial loss on dependents. On the other hand, certain necessary restrictions have been maintained in order to eliminate more effectively the possibilities for speculation. Thus, unmarried women under 23 who are not self-supporting and women married less than five years without children are not considered for more than limited amounts, and then usually on the endowment plan. In such cases it is usually required that the husband be insured in her favor for at least an equal amount.

It is fair to conclude that the mortality experience of women insured in ordinary plans can be made to present as favorable an aspect as that which is now observed among insured men. To do this there must be an appreciation of the changing status of women in the social and economic world. Women are becoming economic producers, and even housewives are so recognized. It is, therefore, a narrow policy which would put unnecessary and harsh restrictions on the insurance of women on the score of sex alone. To obtain satisfactory experience on female lives, their applications must be secured in large numbers by active work on the part of the insurance agent, and not, as heretofore, through the voluntary effort of interested parties having reasons for desiring such insurance. There should be a greater equalization of the sexes from the viewpoint of insurance medicine.

**Cancer in Relation to Life Insurance.**—R. Kingston Fox says that during the past thirty years the mortality from this disease in England and Wales has risen in the case of males 150 per cent. and in the case of females 60 per cent. Cancer now accounts for one in every nine deaths among all adults of twenty-five years and upwards. In women between the ages of forty and sixty years it accounts for one in every five deaths. As regards the insurance of women, the liability to malignant disease of the uterus and breast during the middle period of life has become so great that it is a question whether female lives in whose family histories there is a single such record among parents or brothers and sisters should ever be taken without a rating. The increase of cancer dictates also special care in dealing with evidence of slight derangement of various organs and especially of the digestive system, for it is in this tract that the increase of mortality has been most marked.—Life Assurance Medical Officers' Association, January 7, 1914.

**Causes of Death in Women.**—According to the report of the Medico-Actuarial Investigation as to the causes of death among women, it is found that there are four under which the proportion of deaths increases with the duration of the policy, doubtless largely because of the advancing age of the insured, namely: Cancer and malignant tumors, cerebral hemorrhage and apoplexy, organic diseases of the heart, nephritis and Bright's disease. The mortality from suicide is not materially higher in the first than in the second or third policy year. The proportion of deaths from tuberculosis is comparatively low in the first policy year, increasing to a maximum between the third and fifth year, then gradually decreasing. Spinsters show a lower mortality than other classes of women from the following causes: Tuberculosis of the lungs, pneumonia, nephritis, cancer, cerebral hemorrhage, organic heart disease.—Medical Section, American Life Convention, August, 1913.

# Book Reviews.

Fruchtabtreibung und Praeventivverkehr, in Zusammenhang mit dem Geburtenrückgang. Eine Medizinische, Juristische und Sozialpolitische Betrachtung. Von Dr. Max Hersch, Frauenarzt in Berlin. Price, 6 Mk. Würzburg: Curt Kabitzsch, 1914.

The author amplifies in this pamphlet his ideas on the subject of abortion and preventives of conception which have been already published in the leading German periodicals. He addresses his treatise to the gynecologist with the remark that the share of woman in the social and economic governments and her entrance into the bread-winning classes make it necessary for the gynecologist to keep apace with criminalistic and juristic medicine, trade hygiene, heredity, Socialism, sociology, and the new sanitary systems as well as modern theories on psychology and psychiatry.

Die Heliotherapie der Tuberkulose, mit besonderer Berücksichtigung ihrer chirurgischen Formen, von Dr. A. Rollier, Leysin; mit 128 Textabbildungen; Preis M. 6.60. Berlin: Verlag von Julius Springer, 1913.

Rollier and his disciples for some years past have published in various medical journals the results of their treatment of surgical tuberculosis by exposing the naked body to the air and to the direct rays of the sun. The volume under consideration, of 119 pages, puts these results into book form. The work has attracted great attention, for it challenges flatly many ideas and beliefs which pass for accepted truths, and if Rollier can establish his contentions he will cause a revolution in the treatment of those tuberculous lesions now grouped under the title of "surgical," viz., arthritis, osteitis, tendo-vaginitis, adenitis, dermatitis, etc. After a preliminary review of the history of heliotherapy, the author takes up the theoretical consideration of the identity of the sun's rays which possess healing properties, and the manner in which they exercise them. His thesis is that the ultra-violet rays cause a pigmentation of the skin, and thus permit its penetration by the longer waves. Hence, the sun's rays act curatively not only in superficial but also in deep-seated tuberculous disease. In addition to the direct effect of sunlight on the lesion, the author ascribes to the indirect effect of the mountain climate upon the blood, a share in the healing process. Minute directions are given for the dosage of fresh air and sunshine in the various regions and organs of the body. All apparatus preventing access of light and air is discarded. The book closes with a comprehensive bibliography. It is profusely illustrated with photographs and skiagrams showing the remarkable effect of treatment, but contains no proof as to the correctness of the diagnosis in any case. In other words the importance of the author's conclusions seems to rest upon the correctness of his premises, and these he has neglected to prove.

A Manual of Otology. By Gorham Bacon, A.M., M.D., Professor of Otology in the College of Physicians and Surgeons, Columbia University, New York. New (6th) edition, thoroughly revised. 12mo, 536 pages, with 164 engravings and 12 plates. Cloth, $2.25 net. Philadelphia and New York: Lea and Febiger, 1913.

In this new edition of Bacon's manual the chapters on suppurative labyrinthitis, the submucous operation, and otosclerosis have been revised and enlarged. There is some question as to the advisability of attempting to introduce so much nose and throat work into a textbook of otology, since the former field has become too wide to do it justice, and the result is likely to be sketchy and inadequate. If one discusses tonsils, adenoids, and the septum, he should also discuss accessory sinus disease, hay fever, and new growths; for these conditions are quite as important causative agencies in aural difficulties as those described in this book.

In describing the tests the author fails to mention several ordinarily given for unilateral deafness, notably the Stenger test. He says that some cases of labyrinthitis "have no special symptoms and are discovered only on performing the radical mastoid." Labyrinthitis always gives rise to symptoms which in many cases are violent and can be discovered by careful questioning when taking a history. This is a matter of prime importance. Again, sufficient stress is not placed upon the aural significance of nausea, vomiting, vertigo, and nystagmus. Too frequently these symptoms are ascribed to a stomach disorder, and the modern otologist must do all in his power to teach the general physician not to overlook a possible labyrinthine cause of these reflex acts.

The value of Bacon's work is too well known to need comment, but the worth of the book would be greatly increased, in the reviewer's opinion, by a correction of the imperfections noted.

Diseases of the Heart. By James Mackenzie, M.D., F.R.C.P., LL.D. Ab. and Ed., F.R.C.P.I. (Hon.) Third Edition. Price $5.50. London: Henry Frowde, Oxford University Press, Hodder & Stoughton; New York: Oxford University Press, 1913.

More than three years have elapsed since the last edition of the work under notice was issued. In this period much advance has been made in the knowledge of the heart, which has necessitated the rewriting of the greater portion of the book. It is needless to say that this advance is chiefly due to Mackenzie himself and a great deal of the progress was only rendered possible by the invention of instruments of precision for the purpose of recording accurately heart movements and, of course, especially abnormal movements. Mackenzie and his followers have revolutionized the study of heart movements, in so far that they have made a study of the physiology of diseased hearts and especially of those with abnormal rhythm, whereas formerly this study was merely based on what happens to normal hearts with normal rhythms. By the application of scientific principles and apparatus a few conditions such as auricular fibrillation and auricular flutter can be treated intelligently. As, however, the author points out later investigations have shown how helpless we are in the face of many conditions, and emphasizes the state of comparative ignorance which has existed and still exists, although to a lesser extent, as regards accurate and scientific knowledge concerning diseased conditions, for it must be borne in mind that only recently the fact that in hearts affected by disease their reaction to stimulation is profoundly altered has been recognized. This last edition of Mackenzie's work is well worthy of the author. It is written clearly and without redundance, and ought to be in the hands of all those who wish to keep in touch with scientific progress in the direction of diagnosis and treatment. The book is well printed and the text is illustrated where necessary with a number of illuminative cardiograms.

Gonorrhea in Women. Its Pathology, Symptomatology, diagnosis, and treatment; together with a Review of the Rare Varieties of the Disease which occur in Men, Women, and Children. By Charles C. Norris, M.D., Instructor in Gynecology, University of Pennsylvania; Assistant Gynecologist to the Hospital of the University of Pennsylvania; Physician to the Maternity Hospital, Philadelphia. With an introduction by John G. Clark, M.D., Professor of Gynecology, University of Pennsylvania; Gynecologist-in-Chief to the Hospital of the University of Pennsylvania. Illustrated by Dorothy Peters. Price $6.00 net. Philadelphia and London: W. B. Saunders Company, 1913.

This is by far the most complete work on gonorrhea that has yet been published in English. The first chapter deals with the history of our knowledge of the infection, and is a most interesting and fairly complete account. The references to some of the classical authors are vague and unsatisfactory, and compare most unfavorably with the admirable bibliography which is given with the later and more distinctly medical items. Then follow chapters on bacteriology, pathology, and pathogenesis. The two succeeding chapters are on sociology and prostitution, and contain a wealth of material not to be found in any other single volume. Prophylaxis is dealt with at some length, and chapters follow on the examination of patients; gonorrhea of the external genitals, metritis, vaginitis, salpingitis, and ovaritis; treatment and complications; gonorrhea in pregnancy and labor, and the puerperium; gonorrhea in children and the aged; non-genital gonorrhea, and gonorrheal therapy. The author has produced a most thorough study of the subject, and one which will prove of incalculable service to the practitioner, the specialist, and the student of sociological problems. The references to the literature are very numerous, and it would seem that no published case has escaped the author's eye. The book is well printed and handsomely bound.

# Society Reports.

## NEW YORK ACADEMY OF MEDICINE.

*Annual Meeting, Held January 15, 1914.*

THE PRESIDENT, WILLIAM M. POLK, IN THE CHAIR.

**Edward N. Gibbs Memorial Prize.**—Dr. HERMAN OTTO MOSENTHAL was awarded this prize.

**Appropriation for the Library.**—It was moved, seconded, and carried that the sum of $3,500 be appropriated for the needs of the library.

**Report of Names of Deceased Members.**—The following names of Fellows of the Academy who had died during the year 1913 and had been reported at the Stated Meetings of the Academy were as follows: Drs. Algernon T. Bristow, Elsworth Eliot, Sr., Cleveland Ferris, George Fisher, Richard Pierce Francis, Walter C. Gilday, Frank Hartley, Archibald Ezekiel Isaacs, Nathan Jacobson, Francis Parker Kinnicutt, Charles McBurney, Prince Albert Morrow, Edward Leroy Oatman, Kingman Benjamin Page, Charles Hermann Reinsberg, James Percival Tuttle, Richard Van Santvoord, and Joseph Caddington Young.

**A Critical Study of Intestinal Stasis, Including New Observations and Conclusions Respecting the Causes of Ileal Stasis.**—Dr. JAMES T. CASE of Battle Creek, Mich., presented this paper. He declared that the fact of the common occurrence of intestinal stasis must be recognized and its importance conceded. The essential theme in Lane's teachings related not so much to kinks or colectomies, or short circuitings, as to the danger of continued stasis in the human drainage system and the necessity for doing something, medically or surgically, to relieve it. Great credit was due to Lane for the wave of interest in intestinal stasis which had swept over England and America. Apparently it was not the poisons themselves that concerned them, but the failure of the defenses of the body which should be constantly active against these poisons, and the rational course was to discourage the formation of the poisons in every possible manner, particularly through lessening the sojourn in the intestine of the material from which the poisons were formed. The relation of pyorrhea alveolaris and other forms of mouth infection to infectious processes within the bowel had been well established. The consensus of opinion brought out in a recent debate before the Royal Society of Medicine in England seemed to be that the poisons of alimentary toxemia were in many instances chemical protein derivatives of comparatively simple formula. There was evidently a certain relation between alimentary toxemia and diseases of the eye, certain skin manifestations, and various other constitutional symptoms. These things were generally accepted. The part of the subject still under controversy related to peritoneal bands and their relation to kinks, intestinal stagnation, increased putrefaction, increased formation of poisons, etc. The essayist stated that through his institutional connections he had had unusual opportunities for the roentgenological study of intestinal stasis. About four years ago the tentative rule was made that every case for which laparotomy was recommended should be subjected to a thoroughgoing roentgenological examination before being sent to the operating room. The results in the way of help to the surgeon, especially in connection with the problems of intestinal stasis, had warranted the continuance of this rule. Not only had the *x*-ray findings been checked up by the report from the operating room, but the roentgenologist had made it a point to be present as one of the assisting surgeons at as many of the laparotomies as possible. It was extremely interesting to study the operative findings relating to kinks and torsions of the ileum and colon in connection with the motor function of the bowel, and particularly to note the frequency with which adhesions of the terminal ileum and colon were present in cases in which, from the bismuth meal examination or other clinical investigation, intestinal stasis had not been suspected, and in which there was no reason to believe the existence of ileal stasis. Relatively few of the patients were operated upon directly for the relief of intestinal stasis. There were exceptional cases in which dietetic and other non-surgical means had been tried thoroughly and in which short-circuiting, especially when an artificial ileocecal valve was made, as first advocated by Dr. J. H. Kellogg, had resulted in most marvelous improvement. The real pernicious stasis, the intestinal stagnation which was really damaging, was not colonic stasis, but ileal stasis. Within the last four or five years Lane had dwelt more on ileal stasis and agreed that it was of far greater importance than colonic stasis. In every single case in which an *x*-ray examination had been made by him following the short-circuiting operation, he had observed retrograde peristalsis in the colon. In many of these cases there was also a reflux of colonic contents through the anastomotic opening into the small intestine, and the resulting stasis in the small intestine converted the terminal ileum into a veritable colon so that the patient, instead of having a colon five feet long, possessed a colon of indefinite length. In some such cases the terminal ileum was found to have a calibre of the colon itself, so that it was not easy to differentiate ileum from colon. After discussing the embryology and his findings in regard to ileal kinks at operation he concluded that (*a*) there did exist certain forms of obstructing Lane's ileal kinks. But (*b*) there were numerous other cases which had come to operation in which kinks had been found where a carefully conducted *x*-ray examination had shown the absence of ileal stasis and where there were no other clinical evidences upon which to base a belief that ileal stasis existed; (*c*) there had been a certain other class of cases in which ileal stasis had existed and no adhesions had been found. Study of these cases led to the conclusion that a large proportion of cases of ileal stasis was due, not to kinking or adhesions of the terminal ileum, but to incompetency of the ileocolic valve, or to spasm of the ileocecal sphincteric mechanism, or to a combination of the two factors. The behavior of certain striking cases which had passed under roentgenological and surgical observation strongly supported the idea that the normal ileal stasis was increased in all conditions leading to spasm, probably most marked in acute appendicitis, less marked in chronic appendicitis. It was probable that other conditions, perhaps even adhesions of the terminal ileum, might also produce stasis which, up to a certain degree, was normal in the terminal ileum. As a new and additional cause of ileal stasis, the writer had suggested incompetency of the ileocolic valve. Kellogg, Groedel, Dietlen, Rieder, and others had since agreed on the importance of recognizing this condition. Their observations gave confirmation of the belief that the normal ileocecal valve was thoroughly competent. Without exception, when the ileocolic valve was found incompetent to the enema on one occasion, it had been found incompetent at all subsequent observations. Ileocecal valve incompetency had been observed not only after the clysma, but also after the ingestion of the bismuth meal. In more than fifty cases the writer said he had definitely proven the regurgitation of ingested bismuth from the colon back into the ileum, no new bismuth meal having been taken in the interim. In every instance in which the ileocecal valve proved to be incompetent to the enema, at operation the surgeon found gas or fluid distension of the terminal ileum in spite of thorough efforts at preoperative bowel cleansing. In cases in which the ileocecal valve had proven competent to the enema, the surgeon had in the great majority of cases confirmed this observation by the author's method. Still further proof of the normal competency of the ileocecal valve was presented in the fact that the incompetency thus shown by the *x*-ray study and proven at operation had been cured in a number of cases by a simple surgical procedure. This ingenious operation for restoring the competency of the ileocecal valve had been described in a recent paper, read before the American Roentgen-Ray Society at its annual meeting, held in Boston, October, 1913. This operation consisted in placing several sutures in such a manner as to restore the invagination of the bowel without narrowing its lumen. The operation was practically bloodless, did not involve opening the peritoneum, and was quickly accomplished. The operation was primarily devised and performed for the relief of marked ileal stasis, but it had been found applicable to cases in which no ileal kink was found, and Dr. Kellogg felt that the operation had a more extensive field than was recognized, and he had performed it up to the present writing in just one hundred cases. In the majority of instances ileocecal valve repairs had been done in the course of operations for other causes, where the routine *x*-ray examination had shown ileal stasis to exist and in which it appeared that the ileocecal valve incompetency was the cause of the stasis. The most convincing argument as to the efficacy of this operation was that in all these operated cases

in which ileal stasis existed before operation post-operative studies have shown that in every instance the emptying time of the terminal ileum had been markedly diminished and in the majority of cases it had been reduced to seven or eight hours, while other clinical evidences of ileal stasis had disappeared.

The Practical Application of the Roentgen Method to Gastric and Duodenal Diagnosis.—Dr. ARIAL W. GEORGE of Boston, Mass., read this paper, in which he reviewed what he had found of practical value in the study of gastroduodenal lesions. He stated that while the fluoroscope had its valuable applications, the careful production of serial plates frequently gave more important evidence than one could find on the fluoroscopic screen. Insufficient technical experience and a tendency to allow the clinical evidence and the clinical diagnosis to bias the Roentgen diagnosis were the source of many errors and had led to a charge of inefficiency of the method. The greatest value in the Roentgen diagnosis of the gastrointestinal diseases was the possibility of classifying cases seen into medical or surgical categories. It was only in the cases which might be classified as surgical that the writer felt that they were able to obtain really positive Roentgen evidence. With regard to acute, simple peptic ulcers, if one relied upon the Roentgen evidence alone a considerable number would be overlooked. If one had "good luck" he might find the so-called "incisura," or sharp incutting of the bismuth contour. Some investigators were willing in such cases to make an inferential diagnosis of gastric ulcer from the presence of tender points and six-hour residue alone. The more evidence that he had collected on this subject the more he had felt convinced that six-hour gastric stasis was the least important factor in Roentgen bismuth diagnosis. In his opinion six-hour bismuth stasis was in itself merely a symptom; any attempt to make a diagnosis from its presence was little more than inferential. It was against their method of inferential or indirect diagnosis against which he wished to protest. The presence of gastric spasm was one of the most potent sources of error with which one had to contend. It might be due to gastric or duodenal ulcer, gall-bladder disease, appendicitis, renal calculus, diseases of the nervous system, chronic morphine and nicotine intoxications, the vague clinical symptom complex, known as vagotonus, and other causes. With such a variety of causes it was obvious that spasm was merely an inferential bit of evidence. The positive diagnosis of acute, simple, peptic ulcer was frequently impossible. With chronic gastric ulcers the situation was quite different. Here there was a production of scar tissue, or the presence of considerable erosion and penetration. In these cases the bismuth outline would show excrescences, out-pocketings, niches, and hourglass contractions. With regard to the last, one must always be on guard against a purely spastic pseudo hourglass formation. Usually repeated examinations would clear up the diagnosis. The evidence of perigastric adhesions was usually best obtained by fluoroscopic examinations. Likewise the fluoroscopic method was of value in observing chronic ulcers when found in the cardiac or median portions of the stomach. When one came to the region immediately adjacent to the pylorus, positive pathological changes could be seen constantly on the plates, which were too small to be seen on the fluoroscopic screen. By means of plates taken in the lateral position, views might be obtained of the anterior and posterior walls of the stomach, and a lesion detected which could not be observed in any other way. In regard to syphilis of the stomach, the writer said that as yet he had failed to find a single case of gumma of the stomach, still one must guard against its possibility. Cancer of the stomach was still the most deplorable condition of the gastrointestinal tract. Patients were often made so comfortable by medical means under a mistaken diagnosis that they easily passed far beyond the operative stage. They must try to diagnose cancer before a positive diagnosis could be made by clinical methods if the patient was to have the advantage of an early and radical operation. In the employment of the bismuth Roentgen method they had a positive aid. This method was especially important in that large number of cases in which the carcinoma was situated in the fundus of the stomach. Here there was no pyloric obstruction and positive clinical evidence was usually entirely lacking. They were discovering many of these overlooked cases and as the technique of Rotentgenology advanced they would find more and more. It was possible to demonstrate on the plates a cancer as small as an average ulcer would be. This type of lesion was so small and so early that in the majority of instances there was no marked change in the gastric secretions. The next important and most easily diagnosed condition was duodenal ulcer. Of all duodenal ulcers 95 per cent. appear on the superior surface of the duodenum with the cicatrix extending either posterior y or anteriorly, or both; but rarely on the inferior surface. Anatomically the first portion of the duodenum in normal individuals always presented the same smooth, regular appearance, and this could be demonstrated in every normal individual as a regular smooth bismuth shadow, of a characteristic shape and outline. If a normal condition could be demonstrated in every normal individual, then the presence on the plates of a constant defect in the cap meant a real pathological condition. No case of duodenal ulcer should be operated upon unless the bismuth examination showed a definite, constant deformity of the "bishop's cap." Every duodenal ulcer which was more than a simple peptic erosion had a sufficiently deep callous to deform the bismuth contour. Every case which finally came to a physician for help already had an abundant cicatrix. In this connection the negative diagnosis was as valuable as the positive. Every patient in whom a normal duodenal cap could be demonstrated had no indurated or surgical ulcer of the first portion of the duodenum. This fact had been demonstrated time and again. In most cases where there had been repeated infections of the gall-bladder, adhesions would usually form, and these would be frequently demonstrated by their attachments to the antrum of the stomach, the first or second portions of the duodenum, the hepatic flexure, or the transverse colon. Occasionally, but not often, the shadow of an enlarged gall-bladder could be seen, but this was not definite enough to warrant any positive diagnosis. The most positive condition they had demonstrated was that of the gallstones themselves. He believed with the further development of this field of work they would be able to demonstrate stones in nearly every case in which there had been repeated infection. In conclusion Dr. George believed that by means of the Roentgen bismuth examination of chronic gastrointestinal diseases one could often obtain positive diagnostic evidence which was unobtainable by any other means. The Roentgen examination should always be preceded by a thorough general physical and laboratory examination.

Dr. WILLIAM H. STEWART said that after seeing this beautiful demonstration he felt that the end of exploratory laparotomy was at hand. They must, however, be conservative and advance slowly, as this was a comparatively new field and invited considerable criticism. The fact that their mistakes and not their successes were heralded near and far was evidence that the importance of the work was being recognized and given a prominent place among their means of diagnosis. The speaker said that he was a firm believer in considering the Roentgen diagnosis as only one of the means toward reaching their conclusions and that it should always be combined with the clinical findings and laboratory reports; this was particularly true of diseases of the gastrointestinal tract, and was well illustrated in the necessary associated knowledge of gastric analysis. One of the greatest obstacles with which they had to contend, as Dr. George had mentioned, was the use of the Roentgen examination before sufficient experience had been obtained to make correct interpretation, and right here he wished to send out this warning. The general use of the *x*-ray for fluoroscopy, such as was occurring in this country to-day, without proper protection was bound to lead to disaster. While he believed in the direct positive method in acute peptic ulcers, or erosions of the stomach, one must be guided by the "symptom complex" if one hoped to make a correct diagnosis; in chronic ulcerations one was not confronted by so great a difficulty, as here one could obtain direct ocular evidence. There was one thing that the Roentgen ray had done and that was in the diagnosis of carcinoma. The speaker made an urgent appeal for the earlier use of the Roentgen ray in this suspected lesion. The recognition of the presence of duodenal ulceration was now within the grasp of the roentgenologist. Hypermotility, when not caused by carcinoma of the fundus, or achylia gastrica, or chronic gastritis, associated with actual persistent deformities in the bulbous duodeni, made the diagnosis comparatively easy, and should be more readily taken advantage of by clinicians in any questionable case. There seemed to be considerable

difference of opinion as to when ileal stasis was present. Some writers claimed that no case was one of ileal stasis unless the bismuth meal was retained in the ileum at least twenty-four hours. He believed, however, that no hard and fast rule could be made, as it depended in a great measure upon the amount of obstruction. As a matter of fact the important point to be cleared up was what was causing the retention. Chronic appedicitis, with accompanying adhesions, was in his experience the most common cause of ileal stasis. Competent roentgenologists had now reached the goal where they could demonstrate a patent appendix and ascertain whether it was bound down in an abnormal position by adhesions and whether these accompanying adhesions were causing an obstruction of the ileum.

Dr. Byron Clary Darling said that they had all been impressed with the advances that had been made and they had the feeling that the possibilities were great. They were all developing technique. Dr. Case's work showed a certain percentage of error, and the source of these errors had not yet been discovered.

Dr. Louis Gregory Cole said that in 1906 he detected his first case of ileocecal insufficiency, and he believed this to be the greatest cause of ileal stasis.

Dr. Albert Charles Geyser said that from the various roentgenograms thrown upon the screen it was evident that the *x*-ray picture was a thing of the past. Instead they had not quite so ornamental but certainly much more useful clinical evidence of the pathological lesion. The practice of medicine had made great strides of late, but could such advancement have been brought about without the intervention of the refined diagnostic technique. The roentgenogram of to-day, when interpreted by a competent individual, especially if he was given all the clinical findings, was the most valuable asset the physician and surgeon possessed. From what had been seen and heard it must be self-evident that no one but a thorough physician, surgeon, and roentgenologist, all combined in one man, could or ought to undertake either the production or the interpretation of a plate. Dr. Cole had laid great stress upon the insufficiency of the iliocecal valve. Personally, he had not been convinced of the seriousness of such a defect, if a defect it really was. The very fact, as Dr. Cole had stated, that 10 per cent. of all valves examined were defective led him to take a rather optimistic view of it. Other things being equal, he said he could see a conservativeness in such a weakness and it might act occasionally as a real safety valve.

Dr. Anthony Bassler said it was one thing to make a diagnosis, but another to make one that was right. In the hysteria of intestinal stasis that Mr. Lane had set off it was a delight to hear Dr. Case bring some sensible balancing data. His point that these kinks and bands but rarely had to do with actual stasis was an important one for surgeons to remember. In his experience the so-called ileal kinks were a most common finding and yet they but seldom caused stasis mechanically. To the added theory of ileal stasis that Dr. Case had mentioned due to the incompetence of the ileocecal valve he said he would add that of primary toxemia in the alimentary canal wherein the stasis was caused by degeneration in the sympathetic nerves and ganglionic cells. In this way the nerve balance of tonus was interfered with so that deficient motility and some degree of dilatation with attenuation of the gut was responsible for the delay in transit of its contents. Some three years ago he presented his belief that diagnosis of gastrointestinal conditions by the *x*-ray should not be made on the basis of the so-called indirect method and suggested that there should be a definite change in the anatomy in pathological ways. He met with a tremendous opposition on the part of roentgenologists, but he was glad to see his idea, which was the only safe standard, was now coming about. He was definite in the belief that one could not make a diagnosis of gastric or duodenal ulcer along such lines as rapid emptying of the stomach, reverse peristalsis, and so forth, and he was pleased that Drs. George and Cole have accepted his belief that the safe way of diagnosing these conditions was along the lines of pitting, diverticula, or filling defects. He said that recently a very well-known roentgenologist and serious worker featured the diagnosis of gastric and duodenal ulcer along the lines of stasis in the stomach. In 120 cases of proven duodenal ulcer, stasis was observed by Dr. Bassler in 35, making 28 per cent. From the Mayo clinic Dr. Eusterman had just reported 776 cases of duodenal ulcer, also proven by operation, with stasis present in only 26 per cent. In Dr. Bassler's experience stasis was present in gastric ulcer in 34 per cent., whereas in 324 cases in the Mayo clinic it was present in only 29 per cent. It was important to state in the cases of the Mayo clinic and his own that the diagnosis of stasis was made by test meals, the only sure way to do it. Therefore, one set of men feature the diagnosis on the basis of rapid exiting, another by delay in exit, and the truth was that neither one were characteristic of ulcer, although either one might be present. He did not desire to throw any cold water on the *x*-ray means of diagnosis, for the *x*-ray had been a good friend to him, but he did desire to chill the extreme enthusiasm, which was liable to carry men afield. They should be conservative and with such tremendous advantages in gastrointestinal diagnosis that the *x*-ray gave they could afford to be conservative. Lastly, in diagnosing the *x*-rays were a good cane, but they were not crutches, because history, physical examination, laboratory, and a brain skilled in the deductive ability of gastrointestinal conditions were important too.

## MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

*Stated Meeting, Held December* 15, 1913.

The President, Dr. Reynold Webb Wilcox, in the Chair.

**Chronic Intestinal Stasis, Medically Considered.**—Dr. William Van Valsah Hayes read this paper. He said there were some who believed that practically all chronic illness has its origin in the intestine, and among these was Sir Arbuthnut Lane. That one whose life had been spent chiefly in surgical work should advance such a claim was certainly startling; yet we would be foolish indeed if we did not carefully weigh all the evidence brought forward by him. His views were misunderstood and disregarded by many, but that the conditions described by him actually existed could be readily confirmed by any well-trained physician having the opportunity of studying his cases thoroughly by modern methods, and of following those requiring surgical relief to the operating table. It was his own belief that, after duly weighing Lane's work in this line the profession would agree that his contribution to medicine was of the greatest possible value. In a recent address he (Lane) had stated that by chronic intestinal stasis he meant that the passage of the contents of the intestinal canal was delayed sufficiently long to result in the production, in the small intestine especially, of an excess of toxic material, and in the absorption into the circulation of a greater quantity of poisonous products than the organs which converted and excreted them were able to deal with. This stagnation of the intestinal current might be brought about in different ways; either with or without the presence or formation of the "evolutionary bands" and membranes described in the literature of the subject. The delay of the contents of the small intestine, also of the stomach and duodenum, resulted, according to Lane, in their infection by microorganisms and in the development of chemical changes in the stagnating material. These changes, in addition to existing mechanical effects, brought about an engorgement of the mucous membrane about the pylorus and along the lesser curvature of the stomach or in the duodenum, which might terminate in ulceration, perforation and, later, cancer; or an infection of the ducts of the pancreas, which might produce degenerative inflammatory changes and their consequences. The speaker gave a long list of the chief symptoms and signs of intestinal stasis as described by Lane, and then said that the marked symptoms in his own cases had been weakness, loss of weight, headache, nervous irritability and emotional states, lack of concentration, drowsiness, numbness, palpitations, poor circulation, soreness of joints, constipation, and in cases with gastric complications, bad taste, belching, regurgitation of food and acid fluid, erosion of the teeth, pain between the shoulder blades, nausea, and vomiting. Ulcer near the pylorus had been a rather frequent complication. The marked physical signs had been pallor, with or without anemia, a sallow color or slight pigmentation of the skin, cold, moist hands and feet, and the following abdominal signs, which were very constantly present and, taken with the toxic symptoms, made the diagnosis extremely simple: (*a*) Dilated duodenum, shown by a marked tympanites in the area behind the right

rectus muscle, to the right of the pylorus and situated between the gall-bladder above and the transverse below. The dilated duodenum was readily mapped out by percussion with pressure. (*b*) Pressure paradox. In cases showing a dilated duodenum pressure was made backward and upward for about thirty seconds by the hand placed just below the umbilicus, with the patient in a semi-recumbent or reclining position. This would usually result in the undoing of the duodenojejunal kink present, permitting the duodenum to empty itself. It was often possible to hear and feel the gas escape as it rushed into the jejunum. (*c*) Inflated ileum, as shown by a marked tympanitic note to the left of and below the cecum. (*d*) Corded colon. Frequently the left iliac colon was felt as a rope-like body directly beneath the abdominal wall, and this condition was apparently due to spasm of the portion of bowel just above the sigmoid flexure. To what degree it should be considered abnormal was debatable. Jordan, who had done such invaluable *x*-ray work in conjunction with Lane, had made the statement that the occurrence of duodenal distention was so constant in the subjects of intestinal stasis that he had come to regard it as a trustworthy indication, equally valuable whether positive or negative. In the treatment of chronic intestinal stasis the diet should be suited to the state of the gastric and intestinal digestion. In general, it should be gently laxative, without being coarse or irritating, and should not contain an excess of protein or a large percentage of readily fermenting elements. Exercise of various kinds was of great value. Correct poise or carriage should be insisted upon—the patient should learn to stand and sit with chest thrown forward, chin and shoulders back, and abdomen drawn upward. A suitable belt, corset, or spring support was indispensable in most cases, the aim being to prevent, as far as possible, duodenal and iliac delay, and to equalize and increase somewhat the intraabdominal pressure. In the way of medication bland laxatives were chiefly required, liquid paraffin or Russian mineral oil of superior quality holding the first place in usefulness. This had the property of rendering the stools soft and of hastening the movement of the food through the small and large intestine. It was not always sufficient by itself, however, and so had to be assisted by other laxatives or suitable cathartics. Colocynth, podophyllin, and similar drugs should not be used, because of their irritant action. An occasional dose of calomel, followed by a bitter mineral water might be necessary. Surgery should not be thought of in the great majority of instances, but was indicated in the marked cases failing to respond to persistent competent medical treatment, provided that the patient had sufficient resistance to render success probable. The paper was concluded with the recital of six cases, studied conjointly by Dr. Hayes, Dr. Quimby and Dr. Bainbridge, which illustrated certain types of stasis.

**Roentgen Examination in Chronic Intestinal Stasis.**—Dr. A. JUDSON QUIMBY said that the Roentgen examination of the intestinal tract to determine stasis or chronic constipation involved the administration of an opaque material, such as bismuth subcarbonate or barium sulphate, in the form of a meal, which was followed in its normal course through the bowel at such time periods as would elicit the functionating of the organ and such anomalies as existed. In his own cases he so arranged the time periods for the numerous examinations as to enable him to roentgenograph such places as it was expected to find causes for stasis in, and at the same time avoid overlooking unusual departures from the normal. In about 50 per cent. of the cases the entire amount of the meal would be evacuated in 54 hours; of the remainder, 30 per cent. in 78 hours, 15 per cent. in 102 hours, and 5 per cent. in a longer period. These percentages were not applicable to the human race in general, but only to the most pronounced cases of constipation. Intestinal stasis might be regarded as beginning in the first portion of the duodenum. Having described the mechanics at this and other points, he said that the normal suspension points of the bowel were the first ones to be subjected to stress when ptosis occurred. In some individuals we might observe abnormal supports at a very early age, and the question had arisen whether such supports were congenital or acquired. We had to-day no proof that they were acquired, while we had evidence that the new-born might have mesenteric bands, short mesenteries, and various kinks of the bowel such as were found on the operating table in adults. He had had the opportunity of examining children of all ages, and in them had found the same roentgenographic evidences of anomalous conditions which occurred in the adult. Those found in the adult, however, had as a rule been more accentuated. A study of a number of cases with post-operative adhesions and adhesions following acute and chronic inflammatory processes in the appendix, gall-bladder, stomach, etc., had led him to conclude that the conditions which arise in the intestine in this class of cases, as compared with those inherited and acquired adventitious obstructive lesions are, with some exceptions, the same. The obstructions might be broadly divided into simple mechanical obstructions, simple, combined with organic changes, and organic obstructions without mechanical phenomena. Obstructions the result of ptosis and adventitious formations commonly occurred, first, along the lesser curvature of the stomach, chiefly near the pylorus. The lesser omentum might contract to such an extent as to pull the stomach upward at this point and materially interfere with the discharge of its contents. The next point at which there was mechanical obstruction, very often of the simple type but sometimes combined with organic changes, was at the juncture of the first and second portions of the duodenum, and, according to his observation, more cases of gastric delay occurred as a sequela of this obstruction than from all other causes combined. The stomach might be so prolapsed as to lie at the brim of the pelvis, yet be equal to the task of elevating its contents to a sufficiently high level for them to pass through the pylerus and fill the first portion of the duodenum; but, if careful observation was made when this occurred it would be seen that a very small amount of material, if any, passed into the second portion of the duodenum. If such a patient were placed in a horizontal position the gastric contents would be rapidly discharged and within the normal period the stomach would be emptied. This was an important point in the diagnosis of the various causes of gastric delay, and one which by many had been overlooked. Such organic changes might occur at the first and second portions of the duodenum as to produce a stenosis which could not be overcome by means of position drainage. The next point at which simple mechanical obstructions, or this combined with organic changes, occurred was at the juncture of the third portion of the duodenum with the jejunum. This resulted in dilatation of the second and third portions of the duodenum, and the difficulty of demonstrating it on the radiograph was greater because of such flexure of the small bowel. Having described conditions affecting the jejunum, the speaker said that as the lowermost cells of the ileum in the normal subject lay below the ileocecal valve, there was a tendency for the material which passed upward through the terminal to mass together, so that we might have, even where there was no stasis, a column-like collection of bismuth passing from below upward into the cecum. When the terminal ileum ascended almost to the hepatic flexure before entering the ileocecal valve this was always the result of adhesions. The cecum might lie in the pelvis, and the ileum descend directly into it. In the last type gravity did not play a part, but backward pressure from the distended colon might maintain an iliac stasis. The obstructions occurring here were of the simple mechanical variety and this combined with organic changes within the wall of the ileum, frequently complicated by a twisted ileum; also of the third type, where there had occurred organic changes such as a tightly bound appendix which, resulting in connective tissue formation and contraction, constricted the ileum. On examination of the terminal ileum with the fluoroscope, with the subject in the horizontal position, peristalsis could be observed and would frequently lead one to believe that there was no iliac kink or other obstruction. In this position the iliac contents would pour through the ileocecal valve so rapidly that as short a period as one hour might serve to empty an ileum which would not clear itself under five hours when the patient was erect. When we realized that even on the operating table, with the abdomen open and the ileum before us, a mechanical ileal kink might be unrecognizable unless special methods were pursued to prove its presence, we could see the difficulties which attended the diagnosis of iliac obstruction of this character without the aid of the *x*-ray. He next passed to the colon, and stated that some time ago he had read a paper on angulations of this portion of the intestinal tract. In it he had described five points at which these commonly occurred as the result of contracted meso-

colon and mesenteric or peritoneal bands. In speaking of the latter he had referred to new-formed supports usually found on the outer side of the ascending and descending colon and commonly assuming the functions of a suspensory ligament. He regarded them as having primarily originated from the mesocolon, and therefore had designated them as mesenteric bands. Dr. Quimby here presented a theory regarding a process of evolutionary development taking place in the formation of these bands, and went on to say that there was a law of physics to the effect that the resistance of a tube, bent at an angle, to a liquid or gas passing through it is proportionate to the degree of this angle. Applying this principle to the onward propulsion of the contents of the bowel, we had a demonstration of what could occur to maintain the element of stasis. In addition to this mechanical obstruction the distortion of the wall of the intestine resulted in interference with the motor power of the bowel by inhibiting the muscle fibers. While he had described five points in the colon at which a contracted mesentery and mesenteric bands were commonly found, these occurred also in other regions; but that it was exceptional that these should produce angulation might be proved by inspection, with the aid of the fluoroscope and roentgenograph, of a patient having them, with such patient in either the erect or horizontal position. He had also described six varieties of angulation occurring in the transverse colon. Stasis in the cecum was very frequent, and was primarily the result of several mechanical factors. The first of these was ptosis of the cecum, and the next was the angulation of the colon which followed ptosis of the hepatic flexure. Later on, mesenteric bands and adhesions intensified the obstruction and increased the stasis. The common location for obstructive conditions was in the sigmoid, and these were the result of contracted mesosigmoid, mesenteric bands, and pelvic inflammation. Several difficulties attended the *x*-ray inspection of the sigmoid, especially that portion of it in the pelvis, the bony walls of which prevented shifting the intestine about sufficiently to determine the adhesions. Stereoscopic plates were an aid in this region, but the most efficient procedure was the manipulation of the lower bowel contents with the patient in the knee-chest and the Trendelenburg position. A very common location for obstruction of the sigmoid was at the level of the pelvic brim, acute angulations occurring here because of the short mesentery, which bound down the sigmoid at this point. Such angulation might be accentuated by a distended rectum forcing the pelvic sigmoid upward and pressing the apex of the angle to the left; thus squeezing it against the bony wall.

**Chronic Intestinal Stasis Surgically Considered—Some Types Illustrated.**—Dr. WILLIAM SEAMAN BAINBRIDGE said that just how far the admirable pioneer work of Lane would lead us, time and further study must determine. We no longer questioned the far-reaching relationship of chronic intestinal stasis to many conditions formerly considered distinct disease entities. Lane, as was well known, had repeatedly emphasized a long series of affections brought about by the enfeebled resistance which the tissues offered to the invasion of microbes. Intestinal stasis presented a wide field for research on the part of the physician and surgeon; at the same time such work opened the door of hope for many a person who would otherwise be doomed to chronic invalidism. Adopting the definition of this stasis which Lane had given, we had practically a question of body drainage to deal with. The great central canal, the gastrointestinal tract, with its side passages leading to reservoirs which we called organs, might be compared to a great drainage or sewage system. Obstruction and retention in one part of the sewage system meant, sooner or later, contamination of the entire area drained by the system; and so with the body, when there was abnormal retention in one part, the entire system eventually became contaminated, for here there were present just the conditions—warmth, moisture and bacteria—which favored the development of toxic materials. There might be not only development of more toxic matter than under normal circumstances, but the absorption into the body-tubes of more poisonous material, and the bathing of the tissues with it. The parts thus affected in time suffered disturbed function, disease and ultimate death. The prevention, therefore, of chronic intestinal stasis, with its aftermath of disturbed function, disease and death, was our prime object in the study of this subject. The vast majority of cases should have been prevented, while hygienic and medical treatment, if instituted sufficiently early, would cure a large proportion. Certainly 9 out of 10, or 19 out of 20, of all cases should not reach the stage calling for surgical intervention. In many instances, unfortunately, there came a time when the plumbing must receive direct attention; when the surgeon, as the expert plumber, must be called in. Whether he should patch and mend, so to speak, the defective drainage system, thus warding off trouble, or whether he should employ more radical measures and eliminate defective parts, was a fine point to be decided according to the exigencies of the individual case. We therefore heard of the conservative and the radical treatment of intestinal stasis; but it should be borne in mind that there was no hard-and-fast distinction between the two terms, for what in one case might seem radical treatment might, in another, be extremely conservative. The physician who waited, fearing to resort to surgery, and by this delay rendered necessary, ultimately, a severe operation, was less conservative than one who, by employing milder surgical measures at first, obviated the necessity for the severer operations. In many cases the drainage system had been neglected until a part of the human plumbing must be removed—that was colectomy; in others it was possible to sidetrack the damaged part—that was short-circuiting. In still others the parts could be patched up; the tubes could be straightened, the angles corrected. It was often difficult to determine to just which type an individual case belonged. In fact, it had to be freely admitted that to-day we were feeling our way along; endeavoring to profit by experience in order to more accurately place the border-line cases. For over seven years, the speaker said, he had been in personal touch with Lane, studying many of his cases with him before, during and after operation, supplementing this observation by actual experience in a large number of cases, and to-day he did not hesitate to short-circuit or colectomize where he felt that less radical measures might not suffice; for, as Lane had shown, to cut bands and to disturb many adhesions gave, in markedly toxic cases, as great a mortality as short-circuiting, if not even greater than this. In a broad way we might classify cases of chronic intestinal stasis under three groups. The first, in which surgery was unnecessary, might be called the medical group, and in the third either a short-circuit or a colectomy was necessary. Between these two there was a group in which it was possible to "patch up" the drainage system and thus effect a cure. The cases which he would present belonged to this second group. It was a question whether some of the cases would not have done better if the short-circuit operation or colectomy had been performed; but at all events we had here a group of patients with all the symptoms attributable to chronic intestinal stasis who had been literally made over through surgical intervention based upon the mechanical causes of intestinal obstruction, as described by Lane. He desired to present briefly the histories of a few cases which had been worked out with Dr. Hayes and Dr. Quimby. After all, the surgeon must substantiate on the operating table the predictions which he had made from clinical observation and *x*-ray examination. In order to do this and to put into indisputable and permanent form the actual conditions found upon laparotomy, it was his practice to have an artist skilled in medical and surgical work stand beside the operating table to study the conditions, step by step, and depict on paper exactly what was seen. In addition, he had present a stenographer, to whom he dictated the conditions found and the procedure employed to correct them. The first case described was that of a male, aged 49, who when first seen by Dr. Bainbridge was in very poor condition and practically starving to death. The clinical diagnosis was almost complete pyloric stenosis; gastric dilatation; duodenal ulcer; ileal stasis; and the radiographic, incomplete pyloric obstruction; organic involvement of the first portion of the duodenum, probably malignant; ileal stasis. The conditions found on laparotomy December 25, 1912, were dilatation of the stomach; almost complete pyloric obstruction; diverticulum of duodenum, with a mass of inflammation about it; marked duodenojejunal kink; adhesions between neck of gall-bladder and duodenum; pronounced ileal stasis; marked Lane's bands; some enlarged glands about the pylorus and back of liver. Operative treatment: (1) Gastroenterostomy, posterior; (2) ileal band cut transversely and sutured longitudinally; appendix removed, though normal; (3) small fibroid of right lobe of liver, at free

margin, excised; liver sutured. After-treatment: Liquid paraffin and supporting abdominal belt. This patient was presented perfectly well; having gained 45 pounds. In case 2, that of a physician aged 40, the procedures were: (1) Pyloroplasty (Ileinke-Mikulicz); (2) duodeno-jejunal bands severed and loop of jejunum fastened to under surface of transverse mesocolon; adherent omentum detached and raw surfaces turned in; appendix, which was long, wound around the caput coli to the extent of four inches, and adherent to a typical Lane's band, removed. Lane's band, two inches from ileocecal valve and constricting ileum, severed transversely and sewed up longitudinally. Mobile cecum fastened into right ileac fossa. In case 3, that of a female aged 52 many adhesions were divided, and longitudinal bands of cecum shortened, and head fixed in normal position; retroversion and retroflection of uterus corrected. This patient was also presented in good health. The histories of four other cases were given; after which Dr. Bainbridge went on to say that it had been his endeavor to demonstrate in a concise manner the existence of the various conditions caused, and the results produced by, chronic intestinal stasis. It should be borne in mind that the *x*-ray plates and the drawings made at the operation must be studied with an appreciation of mechanical conditions. When the subject was in the reclining position, as at on the operating table, these kinks and angulations might not be apparent, and this fact perhaps explained the difficulty many surgeons had in "seeing the kinks." Added experience, however, with due allowances for changes resulting from change of position, had practically eliminated the former doubt concerning the existence of these "crystallizations of lines of strain," as Lane had called them, and the resultant showing of the passage of the contents of the great drainage system of the body.

Dr. Edward L. Kellogg said that the diagnosis of intestinal stasis, when presenting active symptoms, was usually not difficult, as the history, general appearance, and results of physical examination were all quite characteristic. In its treatment, however, it was important to determine the location, character and degree of the mechanical interference; and this was more difficult. In some instances the *x*-ray was essential, but not infrequently we could determine the origin of the trouble with accuracy by means of physical examination. He had repeatedly used Hayes' method of diagnosticating duodenal stasis, and believed it to be a distinct addition to our methods of diagnosis. In applying it he often placed the patient in the Trandelenburg position, finding that thus it was much easier to relieve the kinking when exerting upward pressure upon the lower abdomen. Dilated ileum and dilated and movable cecum were easily recognized, in favorable cases, by the physical examination alone. The "corded colon" seemed to him less probably a pathological condition, for, though it could be palpated, it appeared, sometimes at least, to be merely in a state of collapse, while the real trouble was at the hepatic flexure. Right movable kidney was usually found with prolapsed cecum, and he considered it strong presumptive evidence of that condition. Sometimes fixation of the kidney would relieve stasis due to angulation at the hepatic flexure. Certain cases of ileac stasis were due to prolapsed but movable cecum, and sometimes this condition might be recognized by employing the Trendelenburg position and pressing the cecum upward, so that the gas in the lower ileum would be expelled into the cecum; an adaptation of Hayes' duodenal method. The series of cases reported by Dr. Hayes had been cured surgically, and the speaker said he regretted that he had not told of some of his brilliant results from medical treatment, as some might carry away the impression that he was more inclined to resort to surgical treatment than was really the case. It was certainly most important that we should have clearly fixed in our minds the various non-surgical therapeutic resources at our command, and that in any given case we should be quite sure that the possibilities of each line of treatment had been exhausted before giving it up. Frequently he had known advice to be given in a general way, without definite instructions as to details; with the result that the patient reported no benefit, and that particular line of treatment was considered of no use. In this way one after another our therapeutic resources might be given up without having exhausted the possibilities of any one of them. Personally, he considered abdominal massage of such importance that in many instances he applied the treatment himself, and in many instances, when this was given thoroughly, with an exact knowledge of the points producing stasis, it yielded excellent results. Various exercises which brought the abdominal muscles directly into play were also decidedly beneficial. Sleeping without a pillow, and with the foot of the bed elevated, often relieved the kinking sufficiently to cause marked improvement in the stasis. To control the toxemia he frequently prescribed, with excellent results, large doses of animal charcoal. He also made use of the transduodenal lavage described by Jutte in March, 1912, the effects of which were excellent, and sometimes remarkable. Where in the examination of the stools he had found a marked preponderance of anaërobic bacteria, he had occasionally found it of service to use oxygen, introducing it through the duodenal tube and also into the rectum. In a few cases of profound anemia resulting from infection of the colon with the *Bacillus aerogenes capsulatus* he had found autogenous vaccines advantageous.

Dr. Walter A. Bastedo said that while some doubted the existence of such a thing as chronic intestinal stasis, convincing proof that it was a real condition had been shown here to-night. The diagnosis of such stasis could not be made simply from the fact that the bowels did not move, for in some instances where the condition undoubtedly existed diarrhea was actually present. Again, there were many cases of chronic constipation, which had often lasted for many years, in which none of the evidences of intestinal stasis, in the way of bad effects, were found. In cases of chronic intestinal stasis there were symptoms of poisoning which, in the great majority of instances, were relieved by proper regulation of the bowels. In some cases of such intoxication, however, the regulation of the bowels, mechanical support, and other medical and physical means entirely failed to cure or relieve, and a resort to surgery was required. Last summer he had spent some time with Lane, and he had then become thoroughly convinced of the absolute necessity for operative interference in such cases, and of the complete relief which this afforded. He agreed with previous speakers that always before operation was resorted to, thorough *x*-ray examinations should be made.

Dr. Arthur F. Holding said that in the symposium this evening two commendable features were especially noteworthy. The first was the admirable example of "team work" shown by the representative of internal medicine, the representative of roentgenology, and the representative of surgery. The second was the fact that in each case the entire gastrointestinal tract was carefully examined. In relation to the statements of Dr. Hayes regarding the prevalence of physical signs indicating dilatation of the duodenum, he would say that roentgenological examinations had proved that in many instances there was not a dilated duodenum, but one which was thrown into reflex spasmodic contractions by the stasis elsewhere in the intestinal tract.

Dr. J. Bion Bogart said that he found himself not altogether in accord with the previous speakers. Lest he might be thought ignorant of the subject, he would say that if he was not fairly well informed it had not been for lack of opportunity. He had spent last March at the Mayo Clinic in Rochester, in the daily company of Mr. Schlessinger, lately Sir Arbuthnot Lane's house surgeon at Guy's, and while acting as chairman of the Surgeons' Club he had organized a "stasis" discussion, which was introduced by Mr. Schlessinger and participated in by Dr. W. J. Mayo, Dr. Lund of Boston, and others. Moreover, impromptu discussions were daily and nightly occurrences. On his return to New York he had been present at a "stasis" symposium, on the invitation of Dr. Bainbridge, at which, after addresses by the latter and by Mr. Schlessinger, illustrated by lantern slides, there was a long informal discussion by the gentlemen present, in which he himself had taken part. On November 28 he had had the pleasure, through the courtesy of Dr. Bainbridge, of attending his "stasis" clinic at the Polyclinic Hospital, at which Sir Arbuthnot Lane made an address and operated on two patients, in one case doing an ileosigmoidostomy and in the other a colectomy; while, later, Dr. Bainbridge also did an ileosigmoidostomy. Furthermore, he had had the opportunity of discussing the subject to a limited extent with Lane himself. To all this he would add his own operative experience, which had not been inconsiderable. He had seen, and demonstrated to others, many of the various conditions to which Lane and others had called attention. That there was such a condition as "stasis" he had not the least doubt; but what to do about it was the thing which

puzzled him. Of all those with whom he had discussed this, the crucial phase of the subject, he had found no one so discouraging as Lane himself. He told us that we must cease thinking of Lane's kinks, Jackson's membranes, duodenal and gastric ulcers, gall-bladder and pancreatic diseases, joint infections, etc., etc., and attack the Goliath at its source—the "ileal effluent," and that if the symptoms were unrelieved by a course of the genuine "liquid paraffin" there was nothing left but ileosigmoidostomy, with or without colectomy. These, he informed us, were simple operations, and that the magical cure was certain: and Dr. Bainbridge had shown us half a dozen patients to prove it. Now, he had the most profound regard for the opinions and statements of Sir Arbuthnot Lane, for his past achievements were such as to entitle his claims in the present instance to our most thoughtful attention. He would not say he might not yet prove his case, but that it was at present fully proved he was still unconvinced. In our own country alone there were, as was well known, thousands of enthusiastic surgeons who never lost an opportunity to test any new operation, and the work of these must at the present time have resulted in thousands of ileosigmoidostomies. But where were the reports of these cases? He himself had done one ileosigmoidostomy for "stasis," and his patient was a poor Russian Hebrew woman in most wretched condition—an undoubted case, with all the symptoms we had so often heard related. After the operation she insisted that she was no better than before, but he did not think she told the truth, for it was a fact that her mottled brown skin cleared up and she looked better. Still, however, she complained of alternating constipation and diarrhea, and of much pain, until she left the hospital, four weeks after the operation. Of course, one case proved nothing, but it was a fact, attested by many observers, that reverse peristalsis persisted after ileosigmoidostomy, and we must in many cases have a never-ending vicious circle unless we resorted to colectomy. And here he would say that, while ileosigmoidostomy might be a simple operation, with only a trifling mortality, colectomy was not a simple operation, and in the hands of even the most skillful surgeons must yield considerable mortality. He thought we might all follow Sir Arbuthnot Lane at a respectful distance; by which he meant that we should reserve our ileosigmoidostomies and colectomies for the most desperate cases, though even here one should remember that the more desperate the case, the more doubtful was the outcome. In the meantime what were we to do for that very much larger number of patients, illustrating lesser degrees of stasis, who were not relieved by liquid paraffin and who, in our present state of knowledge, we hesitated to submit to either of the major operations? Lane offered us no other alternative.

Dr. HAROLD D. MEEKER said that the more one studied intestinal stasis—the existing pathological conditions and the etiological and end-result possibilities—the more was one impressed with the vastness of the subject. It had been his privilege to observe most of the cases which had been presented, and the results seen in these, as well as in other cases in which the more radical operations had been done, had dissipated the skepticism in regard to the matter which he had formerly believed justified. Whether or not we accepted the theories of Lane as to the formation of evolutionary bands, the conditions did exist, and the fact remained that when the mechanical interference with the drainage system had been properly dealt with, patients did get relief, if not absolute cure. Dr. Bainbridge had spoken particularly of a middle type of cases in which one or more less radical operative measures were sufficient to effect the desired result. Procedures of this kind, such as dividing bands transversely and suturing longitudinally, anchoring a mobile cecum, relieving fixed points, etc., were assailed by many, who maintained that the old bands and adhesions were promptly replaced by new ones. As evidence that this was not the case in instances uncomplicated by inflammatory bands many patients could now be produced who had been cured or greatly relieved. It was needless to say that careful technique was absolutely essential for success. The kind of abnormal conditions met with in this arbitrary class was bound to be recognized and surgically dealt with by a large number of operators who would not countenance or attempt the more radical procedures, and the fact that so many surgeons were willing to believe in the existence of adventitious bands, yet did not know how to locate or recognize them, suggested that it might be of service to point out the usual situation of those abnormal structures which tended to bring about evolutionary stasis, a condition which should not be confounded with inflammatory stasis. (1) There might be developed a band extending from the pylorus to the under surface of the liver. If it were not too long it would serve a good purpose by affording an additional support for the stomach, but frequently it extended forward in front of the transverse fissure of the liver, involving not only the gall bladder and cystic duct but even the transverse colon. Serious disturbances might thus be caused in any or all of the organs concerned. (2) An abnormal band might cause a kinking at the duodeno-jejunal angle, and render the emptying of the duodenum more or less difficult. (3). A collection of inelastic fibres might develop on the under surface of the last few inches of ileum, and, later, form a distinct ligament, which, contracting, caused more or less deformity of the ileum, the Lane kink. (4). Peritoneal adhesions frequently became fused into a broad band spread out along the outer aspect of the cecum and ascending colon; attaching the latter to the adjacent abdominal wall. Various portions of this band, as well as the varied stages of its evolutionary development, had been given special names by different observers. Thus, we heard of Jackson's membrane, Jonnesco's fold, Reid's band, Treeve's bloodless fold, and the like. (5). Both the hepatic and splenic flexures of the colon might be held at exaggerated angles by contracting evolutionary bands. (6). In the effort to keep the sigmoid out of the true pelvis, nature might bring about the formation of bands on the outer surface of the mesosigmoid; a mobile loop being thus converted into a fixed tube, with more or less variation in its lumen. Very often the left ovary was involved in the adhesions which fixed the lower pelvic colon. There might perhaps be other evolutionary bands, which had been overlooked, but the time would soon come when these types at least must be generally recognized.

A number of lantern slides showing radiographs of various intestinal conditions were presented by Dr. Meeker and also by Dr. James T. Case, of Battle Creek, Michigan.

## Books Received.

*The* MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

MATERIA MEDICA: PHARMACOLOGY: THERAPEUTICS PRESCRIPTION WRITING. For Students and Practitioners. By WALTER A. BASTEDO, Ph.G., M.D. Illustrated; cloth; price $3.50 net; 602 pages. W. B. Saunders Company, Philadelphia and London.

THE AMERICAN ILLUSTRATED MEDICAL DICTIONARY. By W. A. NEWMAN DORLAND, A.M., M.D. Seventh Edition, Revised and Enlarged. 1107 pages; illustrated; flexible leather; price $4.50 net. W. B. Saunders Company, Philadelphia and London.

THE SURGICAL CLINICS OF JOHN B. MURPHY, M.D., at Mercy Hospital, Chicago. December, 1913. Vol. II, No. 6. 186 pages; illustrated; paper; price, per year, $8.00. W. B. Saunders Company, Philadelphia and London.

THE TREATMENT OF RHEUMATIC INFECTIONS. Cloth; 134 pages. Park Davis & Company, Detroit, Mich.

BIBLIOGRAPHY OF THE EDUCATION AND CARE OF CRIPPLED CHILDREN. A Manual and Guide to the Literature Relating to Cripples, Together with an Analytical Index. By DOUGLAS C. MCMURTRIE. First Edition. Cloth; 99 pages. Douglas C. McMurtrie, New York.

THE DANDRIDGE VOLUME. Being a series of papers presented at various times in the meetings of the Cincinnati Research Society and dedicated by it to the memory of its distinguished member—Nathaniel Pendleton Dandridge, M.D. Cloth; 330 pages; illustrated. The Lancet-Clinic Press, Cincinnati.

DENTIST'S DIARY 1914. The Book That Breathes the New Spirit in Dentistry. Cloth. Published by Lehn & Fink, New York.

CLINICAL DISORDERS OF THE HEART BEAT. A Handbook for Practitioners and Students. By THOMAS LEWIS, M.D., D.Sc., F.R.C.P. Cloth; illustrated; 116 pages. Second Edition. Shaw & Sons, London.

LEHRBUCH DER FORENSISCHEN PSYCHIATRIE. By Prof. Dr. A. H. HUBNER. Paper; price 28 mks.; 1066 pages. A. Marcus and E. Webers, Bonn, 1914.

THE CAUSE OF THE SOCIAL EVIL AND THE REMEDY. By ALBERT W. ELLIOTT. Paper; 144 pages. Webb & Vary Company, Printers, Atlanta, Ga.

CLINICAL DIAGNOSIS AND URANALYSIS. A Manual for Students and Practitioners. By JAMES RAE ARNEILL, A.B., M.D. Second Edition, Revised and Enlarged. Illustrated; cloth; 270 pages; price $1.00 net. Lea & Febiger, Philadelphia and New York.

LECTURES ON TUBERCULOSIS TO NURSES. By OLLIVER BRUCE, M.R.C.S., L.R.C.P. Cloth; illustrated; 134 pages; price $1.00 net. Paul B. Hoeber, New York.

LECTURES ON MEDICAL ELECTRICITY TO NURSES. By J. DELPRATT HARRIS, M.D., M.R.C.S. Illustrated; cloth; 88 pages; price $1.00 net. Paul B. Hoeber, New York.

THE HEALTHY MARRIAGE. A Medical and Psychological Guide for Wives. By G. T. WRENCH, M.D., B.S. Cloth; 300 pages; price $1.50 net. Paul B. Hoeber, New York.

THE PATHOLOGY OF GROWTH TUMORS. By CHARLES POWELL WHITE, M.D., F.R.C.S. Illustrated; cloth; 235 pages; price $3.50 net. Paul B. Hoeber, New York.

DISEASES OF THE HEART. By JAMES MACKENZIE, M.D., F.R.C.P., LL.D., Ab. and Ed., F.R.C.P.I. Third Edition. Cloth; 502 pages; illustrated. Oxford University Press, London.

TRANSACTIONS OF THE AMERICAN GYNECOLOGICAL SOCIETY. Vol. XXXVIII. For the Year 1913. Cloth; illustrated; 630 pages. Wm. J. Dornan, Printer, Philadelphia.

MANUAL OF SURGERY. By ALEXIS THOMSON and ALEXANDER MILES. Vol. III. Operative Surgery. Second Edition. Illustrated; cloth; 620 pages; price $3.75. Henry Frowde and Hodder & Stoughton, Edinburgh, Glasgow, and London; Oxford University Press, New York.

DEFECTIVE OCULAR MOVEMENTS AND THEIR DIAGNOSIS. By E. and M. LANDOLT. Translated by ALFRED ROEMMELE, M.B., Ch.B., and ELMORE W. BREWERTON, F.R.C.S. Cloth; illustrated; 99 pages; price $2.00. Henry Frowde and Hodder & Stoughton, London; Oxford University Press, New York.

COXA VARA. Its Pathology and Treatment. By R. C. ELMSLIE, M.S., F.R.C.S. Paper; illustrated; 35 pages; price 60 cents. Oxford University Press, New York.

PROSTITUTION IN EUROPE. By ABRAHAM FLEXNER. Introduction by JOHN D. ROCKEFELLER, JR. Cloth; 455 pages; price $1.30 net. The Century Company, New York.

AMERICAN RED CROSS ABRIDGED TEXTBOOK ON FIRST AID. Woman's Edition. A Manual of Instruction. By Major CHARLES LYNCH. Illustrated; paper; 148 pages; price 30 cents net. P. Blakiston's Son & Company, Philadelphia.

AMERICAN RED CROSS ABRIDGED TEXTBOOK ON FIRST AID. Miners' Edition. A Manual of Instruction. By Major CHARLES LYNCH and First Lieut. M. J. SHIELDS. Illustrated; paper; 186 pages; price 30 cents. P. Blakiston's Son & Company, Philadelphia.

AMERICAN RED CROSS ABRIDGED TEXTBOOK ON FIRST AID. Railroad Edition. A Manual of Instruction. By Major CHARLES LYNCH. Illustrated; paper; 150 pages; price 30 cents net. P. Blakiston's Son & Company, Philadelphia.

AMERICAN RED CROSS ABRIDGED TEXTBOOK ON FIRST AID. Police and Firemen's Edition. A Manual of Instruction. By Major CHARLES LYNCH. Paper; illustrated; 150 pages; price 30 cents net. P. Blakiston's Son & Company, Philadelphia.

ANATOMY AND PHYSIOLOGY. A Textbook for Nurses. By JOHN FORSYTH LITTLE, M.D. Illustrated; cloth; 483 pages. Lea & Febiger, Philadelphia and New York.

SKIN AND VENEREAL DISEASES—MISCELLANEOUS TOPICS. Vol. IX. The Practical Medicine Series. Edited by W. L. BAUM, M.D., and HAROLD N. MOYER, M.D. Series 1913. Cloth; illustrated: 228 pages; price $1.35. The Year Book Publishers, Chicago.

NERVOUS AND MENTAL DISEASES. Vol. X. The Practical Medicine Series. Edited by HUGH T. PATRICK, M.D., and PETER BASSOE, M.D. Series 1913. Cloth; illustrated; 244 pages; price $1.35. The Year Book Publishers, Chicago.

SCIATICA. By WILLIAM BRUCE, M.A., LL.D., M.D. Cloth; illustrated; 175 pages; price $1.75 net. William Wood & Company, New York.

ÉTUDE CLINIQUE DU SERUM ANTITUBERCULEUX DE VALLÉE. Par le Docteur BOUREILLE. Paper; 49 pages; illustrated. At Maloine's, Publisher, Paris.

## Therapeutic Hints.

**The Treatment of Gastric Vertigo.**—A. Robin recommends the following as an effective remedy in cases that do not respond to the use of simple carminatives and antacids:

℞ Magnesium hydroxide, 0.3 gram.
Prepared chalk,
Sodium bicarbonate, āā 0.2 gram.
Powdered nux vomica, 0.03 gram.
Powdered belladonna root, 0.02 gram.

This powder is to be taken after each meal, and at bedtime.—*Bulletin Général de Thérapeutique.*

**The Treatment of Chlorosis.**—Albert Robin points out that one of the primary indications in this condition is to check the excessive functional activity of the stomach. This is accomplished by the administration of extract of belladonna before meals, and of antacids after meals. The malnutrition is combated with the aid of arsenic administered per rectum or subcutaneously. In the former case the following solution is used:

℞ Fowler's solution, 6 c.c.
Distilled water, 94 c.c.

Of this 5 c.c. are injected into the rectum every morning, following a cleansing enema. For hypodermic use cacodylate of sodium is administered in doses of 5 centigrams daily for eight days, with an intermission of four days, followed by a second series of injections.

Of the preparations of iron Robin prefers the iron and potassium tartrate and the reduced iron, the latter being especially indicated in cases in which a rapid effect is desired. If there is gastric irritability lactate of iron is given. Chloride of iron produces the best results in cases in which there is a hemorrhagic tendency.—*Bulletin Général de Thérapeutique.*

**The Management of Acute Bronchitis in Children.**—G. A. Sutherland states that if in the early stages, as often happens, there is a dry, irritating cough, the indication of increasing bronchial secretion by the inhalation of steam may give great relief. If there is dyspnea from bronchial spasm hot fomentations to the back and front of the chest are indicated. In mild cases of bronchitis no other treatment is necessary than to apply to the chest some stimulating liniment. In more pronounced cases the bowels should be freely opened at the onset of the attack and a simple febrifuge mixture should be ordered, such as the following:

℞ Potassium citrate, 5 grains.
Tincture of orange, 5 minims.
Solution of ammonium acetate, 15 minims.
Camphor water, ad 1 dram.

As regards cough mixtures, it is pointed out that these tend to upset the digestion. If bronchial secretion is defective and there is a harsh, irritating cough iodide of potassium and carbonate of ammonium may be given in doses of two grains each. If bronchial secretion is over-abundant the following may be given:

℞ Tincture of belladonna, 4 minims.
Dilute nitrohydrochloric acid, 3 minims.
Glycerine, 10 minims.
Compound infusion of gentian, ad 1 dram.

If special sedatives seem called for, a convenient form of administration in children is the use of pastilles containing one-fiftieth of a grain of codeine. In the convalescent stage cod-liver oil and hypophosphites give the best results.—"The Treatment of Disease in Children."

### X-RAY OBSERVATIONS ON COLONIC PERISTALSIS AND ANTIPERISTALSIS, WITH SPECIAL REFERENCE TO THE FUNCTION OF THE ILEOCOLIC VALVE.*

By JAMES T. CASE, M.D.,

BATTLE CREEK, MICH.

ROENTGENOLOGIST TO THE BATTLE CREEK SANITARIUM, BATTLE CREEK, MICHIGAN, AND TO ST. LUKE'S HOSPITAL, CHICAGO; LECTURER ON ROENTGENOLOGY, NORTHWESTERN UNIVERSITY MEDICAL SCHOOL, CHICAGO.

According to our present conception the prevailing movement in the proximal colon is antiperistalsis, or, more briefly, anastalsis (Cannon'), consisting of a movement of waves backward towards the cecum. These anastaltic waves do not run continuously for a long time, although a series of waves at the rate of perhaps five a minute can be seen continuing for four or five minutes. Cannon has shown that the condition for the appearance of these waves is normally the pushing of fresh material from the small intestine into the colon.

The distal colon (beginning at the middle of the transverse colon) exhibits as its characteristic activity an onward wave called by Cannon "diastalsis," of which there have been observed in man two kinds—the mass movement, first described by Holznecht,[2] and the slow propulsion of small thumbsize fragments first described by Fischl and Porges.[3]

Haustral churning, according to Elliott and Barclay-Smith,[4] and especially Schwarz and Rieder, is occurring constantly in the distal colon, serving to keep the material in this region thoroughly mixed with the digestive fluids, maintaining its plasticity and thus assisting in its onward progress through the bowel.

Roentgen studies concerning movements of the large intestine have been reported by Holzknecht,[5] Fischl and Porges,[3] Cannon,[5] Rieder,[6] Barclay,[7] Stierlin,[8] Schwarz,[9] Von Bergmann and Lentz,[10] myself,[11] and others.

The extended paper of Professor Rieder published in the *Fortschritte auf dem Gebiete der Roentgenstrahlen*, February, 1912, contains an excellent bibliography and gives extended historical references which it will not be necessary to repeat. My purpose in this paper is rather to describe my own roentgen observations on colonic peristalsis and antiperistalsis and to discuss a number of important related questions, especially concerning the ileocolic valve.

*Colonic Antiperistalsis.*—C. Jacobi[12] first accidentally discovered the evidence of antiperistalsis in dogs under the influence of colchicum poisoning.

Antiperistalsis was later studied in cats by Cannon, who first used the *x*-ray method for this purpose, and in the exposed intestine of certain animals by Elliott and Barclay-Smith.[4] Gruetzner[13] Swiezenski and Riegel confirmed these studies of antiperistalsis. Hemmeter[14] went so far as to claim that small particles traveled as far as the stomach in the course of seven to twelve hours. Boehm[15] by orthodiagraphic means demonstrated that during filling the cecum becomes deeper.

Most of the observers have described antiperistalsis in the proximal colon only, basing their observations on animal experimentation, although it is admitted that it might appear in any portion of the large intestine.

The report of Roith[16] on clinical observations of peristalsis and antiperistalsis of the large intestine in twenty-two surgical cases is most interesting and most convincing. Only one of these was observed by means of the *x*-ray. Roith's work was done with special reference to the length of time material remains in the large intestine. There were five cases of fistula of the ascending colon. An escape of colonic contents began two to four hours after eating and lasted ten to sixteen hours. The stream was steady and there was no means of recognizing the type of peristalsis. There were two cases of fecal fistula at the center of the transverse colon, one of which was observed for more than a year. Fecal discharges occurred once or twice and occasionally three times during twenty-four hours, occurring at the same hour each day and lasting only a short time. The discharge was of a semi-fluid character. In five other cases observed during one and a half years there was a left inguinal colostomy. The results obtained were the same as in the case of the transverse colon fistulæ, the material being semi-fluid. Roith concludes that the normal delay of the contents of the colon in the cecum, ascending and right half of the transverse colon is due either to lack of peristalsis or antiperistalsis which constantly returns material toward the cecum. He believes that the weight of the contents of the colon can have but little effect upon the progress since the specific gravity of the abdominal organs and their contents is practically the same.* The large peristaltic waves which occur at infrequent intervals and transfer the material a long distance serve to move the contents of the colon from the proximal half, where the predominant activity is antiperistalsis, into the distal half where onward peristalsis is the prevailing type of movement.

In three cases reported by Roith, where the ileum was joined to the colon close to the hepatic flexure, bowel contents found their way into the cecum and ascending colon. In one case a cecal fistula of one year's standing persisted after transplanting the

*Read in the Section on Radiology, Seventeenth International Congress of Medicine, London, August 6-12, 1913.

*I shall later report observations which seem to indicate that gravity may be a factor of some importance in the movement of material along the colon.

ileum 20 cm. distal to the fistula, but closed spontaneously after the ileum was reimplanted into the distal half of the transverse colon. In two cases, after resecting the cecum and implanting the ileum 10 cm. beyond the point of resection, there developed a fecal fistula of the stump of the colon; but in the nine following cases in which the ascending colon was excluded, the ileum was implanted into the left half of the transverse colon and no retrograde peristalsis was noted—not even in two cases where the stump of the ascending colon was left open with a drainage tube sewed into it.

FIG. 1.—Roentgenogram showing the banking up of the bowel contents into the proximal colon. Actual antiperistaltic waves were seen in this case.

Roith concludes from the above observations that between the hepatic flexure of the colon and the middle of the transverse colon there is a zone on the distal side of which antiperistalsis does not occur, but on the proximal side both peristaltic and antiperistaltic waves may occur.

Cannon, Elliott and Barclay-Smith, and Jacobi all describe a tonic constriction ring at about this point in the colon which, when stretched as the result of distention of the colon, begins to pulsate. With each pulsation there is sent off an antiperistaltic wave. (See Fig. 1.)

As far as I am aware, these observations have not been, until now, definitely verified in man. According to Cannon, "a variety of *x*-ray observations have been interpreted as indicating anastalsis in the human proximal colon. Thus Stierlin[8] found that the cecum and nearby colon retain longer than any other part of the alimentary canal the mixture used to produce *x*-ray shadows. Furthermore, the sacculi or haustra are in this region often absent or only slightly developed. Bloch[13] and von Bergmann and Lentz[10] have seen in man, by means of *x*-rays, the contents of the cecum and ascending colon quickly forced onward to the beginning of the transverse colon; and then after a short period a definite retrograde movement of the contents which again filled the proximal portion. This to-and-fro shifting may recur rhythmically for some time, and although appearing spontaneously, can be stimulated by palpation. Von Bergmann and Lentz[10] have suggested that the backward movement, or 'retrograde transport' of the contents may result simply from relaxation of the proximal portion after the contraction which forced the material onward. They admit, however, that this return may be hastened by contraction of the transverse colon.

"Although the escape through cecal fistulæ of material introduced distally into the colon clearly demonstrates a backward current in the human large intestine, although the long retention of material in the cecum is good evidence of retarded progress, and although the retrograde transport of material in the proximal colon can be interpreted as due to a backward pressure, nevertheless these facts do not prove the presence of anastalsis in the sense of visible waves passing backward over the intestinal contents. And Hertz[11] has testified to having watched with the *x*-ray the shadows of the human colon for various periods in a large number of individuals without seeing this phenomenon. Even the introduction of an enema (containing bismuth) under a pressure which rendered the entire colon visible did not call forth any anastaltic activity. Rieder[6] has recently been able to bring evidence, however, on the basis of his *x*-ray studies that anastalsis actually does occur in the human colon. While it appeared in the main along the cecum, ascending and proximal transverse colon, it might appear in any portion of the large intestine.

FIG. 2.—Colon filled by bismuth clysma. Note the incompetency of the ileocolic valve, permitting the terminal ileum to fill. Considerable peristaltic activity in the terminal ileum. This roentgenogram was made while actual antiperistaltic waves were being watched in the ascending colon.

These observations on man are wholly in accord with those of myself and Elliott and Barclay-Smith on lower animals."

As roentgenologist to the Battle Creek (Michigan) Sanitarium and to St. Luke's Hospital (Chi-

cago) I have had the opportunity to examine a large number of of individuals by means of the *x*-ray, following a bismuth test meal. In the last thirteen months (June 1, 1913), during which time I have made a roentgen examination after a bismuth meal in approximately fifteen hundred individuals, I have, by means of memoranda dictated at the moment, by roentgenograms, or by tracings, recorded the findings in over sixty cases in which I have actually seen peristaltic waves occurring during the fluorescent screen examination. In thirty-seven cases, antiperistalsis was observed.* The relative frequency with which peristalsis has been observed in these cases may be partially accounted for by the fact that each individual was examined on from six to ten different occasions, in accordance with my method of routine examination elsewhere described.[15]

FIG. 3.—Roentgenogram at the twelfth hour, p.c., showing anastalsis in the large bowel. (Patient has had ileosigmoidostomy.)

In the majority of cases in which I have seen antiperistalsis there have been successive waves originating in the transverse colon near the hepatic flexure at a point corresponding to the seat of the tonic contraction ring referred to by Cannon and others. These waves have not been seen to proceed clear to the tip of the cecum, but only to a point corresponding approximately with the ileocecal junction. The rate at which these waves travel is much slower than the peristaltic waves in the stomach, yet easily and definitely seen on the screen. I have seen at one time as many as five antiperistaltic waves between the middle of the right half of the transverse colon and the cecum. The indentation in the colon shadow produced by these waves has varied from a fraction of an inch to three-quarters of an inch. In six cases this phenomenon of several antiperistaltic waves at one time has been definitely seen. One patient had, a few hours previous to the examination, a dose of seltzer. In the other cases laxatives had been rigorously excluded.

The rhythmical to-and-fro shifting of the contents of the cecum and ascending colon described in man by Bloch[13] and by von Bergmann and Lentz[19] has been seen and verified roentgenographically and fluoroscopically in a number of cases following bismuth injection of the colon. I have also recorded my observations in this type of movement in twelve individuals after bismuth meal, where the existence of antiperistaltic waves may be presumed and yet where actual waves were not discernible. As von Bergmann and Lentz have suggested, it is possible that the backward movement of the contents may result from relaxation of the proximal portion hastened by contraction of the transverse colon. In addition to these twelve cases of antiperistalsis following bismuth ingestion, I have made numerous observations of antiperistalsis following injection of a bismuth or barium clysma.

The existence of a tonic contraction ring in the right half of the transverse colon has been a matter of considerable discussion. It is likely that the exact location of this tonic contraction ring varies with the tonicity of the proximal colon. In most of the cases in which I have observed antiperistalsis the movement began at or proximal to a point near the middle of the right half of the transverse colon.

Boehm[18] states that by means of the *x*-ray he has seen in human beings a narrowing of the transverse colon usually to the right of the midline with undivided contents between it and the cecum, and with segmented masses between it and the sigmoid. Aside from my own records, the above observation by Boehm is the only *x*-ray study on this point in man concerning which I have found a published statement.

FIG. 4.—Roentgenogram made fifty-two hours p.c., illustrating a mass movement in progress.

Inferential evidence of the existence of this tonic contraction ring is afforded by numerous clinical observations among which the following may be especially noted:

*In my earlier work I recorded my observation of antiperistalsis both after bismuth meal and after bismuth injection. Later only bismuth meal observations were recorded.

Roith has measured very carefully the capacities of the several portions of the colon after death. His measurements confirm his observations made during abdominal operations, viz.: that on an average the cecum and ascending colon contained

Fig. 5.—Shows the same case a few seconds later.

more than twice as much as an equal length of the transverse colon and three and one-half times as long as an equal length of descending colon.

(b) The content of the cecum and ascending colon is soft and mushy. The content of the distal colon may be firm and it may be even of the same consistency as the content of the sigmoid.

Boehm, experimenting on cats opened under Ringer's solution, saw a definite contraction ring corresponding to the ring of Cannon. From this ring peristaltic waves traveled toward the rectum and antiperistaltic waves toward the mouth. The antiperistaltic waves were livelier than the peristaltic waves. This ring disappeared and reappeared from time to time.

By means of the *x*-ray I have seen this tonic contraction ring in a number of instances, perhaps twenty. One of the clearest cases was that of Mrs. N. W. (see the appendix for full details). Figure 1 shows the appearance of the colon shadow in this case, which I have interpreted as indicating the presence of a tonic constriction ring. In this instance there was a persistent constriction at about the junction of the right and middle thirds of the transverse colon, seen repeatedly in the same case. Occasionally it relaxed, but then only for a short time. This patient had a mild form of chronic bowel obstruction, but that no organic hindrance was present was shown later during an operation for another cause.

Notwithstanding the statements of various observers would seem to indicate that antiperistalsis does not exist except to the right of a certain point in the transverse colon, I have made several observations which clearly show evidence of antiperistalsis in the distal colon. I have, on one occasion, seen a bolus of ingested bismuth the size of a banana carried from the pelvic colon backward into the left half of the transverse. This occurred in a patient who suffered from chronic constipation for which no other cause could be found than a very severe colitis. The appearance of this bismuth bolus corresponded in all but direction to the mass movement first described by Holzknecht and later to be discussed at length in this article. On four other occasions I have seen smaller boluses of bowel content, varying in size from a filbert to a walnut, carried from the iliac colon backward as far as the splenic flexure. The rate of progress approached that of peristaltic waves in the stomach. These cases had no symptoms of serious bowel obstruction.

Anschütz,[19] Kreuter and Roith[16] have observed that in patients with obstructing tumors of the pelvic colon, gangrene of the walls of the cecum may occur. It was noticed in several cases that the distal part of the large intestine near the tumor was contracted, whereas the cecum was very much distended, sufficiently so to even cause gangrene of its walls. This condition must have been due to stasis, the result of exaggerated antiperistalsis. In other cases, enemas containing lycopodium were given an hour before appendectomy and lycopodium was found in the cecum at the time of operation. In still other cases colored enemas were administered and later the colored fluid appeared in the fistulous openings in the cecum.

At the midwinter meeting of the American Roentgen Ray Society, Western Section, February 22, 1913, Chicago,[20] I called attention to exaggerated antiperistalsis as a sign of serious bowel obstruction. In every case of carcinoma of the colon in

Fig. 6.—Roentgenogram made within a few seconds after Figure 5.

which I have made roentgen studies, I have been able to demonstrate the presence of this exaggerated antiperistalsis. I have seen it occur in all parts of the colon and have presumed that the presence of antiperistalsis under these conditions was

analogous to the presence of antiperistalsis in the stomach, as first roentgenographically described by Jonas. Exaggerated antiperistalsis in the colon has also been recognized in spastic constipation.

Another evidence of antiperistalsis is the frequently observed filling of the large intestine after ileosigmoidostomy as will be illustrated by the following cases:

FIG. 7.—A mass peristaltic movement occurring in the left half of the colon.

Mr. B., examined October 1912. Three years previously the patient had undergone an ileosigmoidostomy for benign obstruction of the colon in the region of the hepatic flexure. The bismuth meal passed out of the stomach within six and one-half hours, passing rapidly to the lower right quadrant of the abdomen, where it filled the sigmoid loop and distended the rectum before the end of twenty-four hours. The patient was very anxious for a bowel movement, but had resisted until an observation could be made. After the evacuation I again observed him and found that only the rectum and ampulla had been evacuated; nothing above. At the end of thirty-six hours, bismuth-mixed contents had backed up into the blind end of the colon further than the splenic flexure. There was still bismuth in the dilated lower end of the ileum. At the end of forty-six hours all the bismuth had been discharged except that which had backed up into the descending and transverse colon. Repeated enemata were given in the attempt to rid the colon of the remaining bismuth, but without success. Later, however, after still further enemata, the colon having been cleared, a bismuth clysma was injected which passed clear around the colon as far as the hepatic flexure. Following the clysma, the patient was able to evacuate the colon completely.

Case of Mrs. A. E.—Three months previous to the present test, the patient had an end to side ileosigmoidostomy after division of the ileum. By the fourth hour after the meal, some of the bismuth had already entered the colon and had begun its retrograde movements. The stomach was just emptying. At the seventh hour, the small intestine was empty; the rectum and ampulla were widely filled. The iliac colon was empty. The descending colon was filled. At the tenth hour the head of the bismuth column had backed up as far as the splenic flexure. At the twenty-fifth hour the colon was filled from the middle of the transverse to the rectum. At the thirty-fifth hour, the patient's bowels having meanwhile moved, the left half of the transverse, the splenic flexure, and the descending colon were still well filled. Below this point, the bowel had been evacuated. At the fifty-first hour, the colon was entirely empty except for a residue in the left half of the transverse and in the splenic flexure. After cleansing enemas, the bismuth clysma was then injected. The head of the bismuth column reached the cecum without hindrance. Immediately following the patient was able to expel the enema almost *in toto*, only a few traces being left in the cecum.

The two cases just cited are only two of the many examples that might be quoted.

In every case in which I have made an examination following ileosigmoidostomy (three months to three years following the operation), I have observed this retrograde peristalsis in the left half of the colon. Although I have not seen in any case actual definite waves, that the retrograde movement is not due simply to an overflow of material from the pelvic colon is shown by the fact that frequently a small bolus of bismuth-mixed bowel content will find its way up into the transverse colon before the distal colon has had time to fill. (See Fig. 3.)

Summarizing my own *x*-ray observations, (1) I have seen in man the tonic constriction ring in the transverse colon just to the right of the midline, described by Cannon and others in animals. From this tonic ring slowly moving antiperistaltic waves have been definitely seen to pass rhythmically toward the cecum. (2) Definite rapid antiperistaltic movements resembling in every respect but direction the mass movements described by Holzknecht have been seen in the iliac and descending colon. (3) Following ileosigmoidostomy, retrograde peristalsis in the colon has been observed in every case examined, without exception. (4) Exaggerated antiperistalsis may be regarded as a sign of serious bowel obstruction and may be expected in spastic constipation and obstruction from benign or malignant processes. It is especially valuable as an accessory sign in carcinomatous obstruction in the bowel.

FIG. 8.—This case illustrates a ring peristaltic movement traversing the colon from ileocolic junction to splenic flexure.

The relation of antiperistalsis to the function of the ileocecal valve will be discussed later.

*Mass Peristalsis.*—Mass peristaltic waves were first seen by Holzknecht,[2] who described two cases. In the first case the haustral segmentation was seen

to disappear, after which the contents of the transverse colon passed on into the descending colon, where the appearance was that of a sausage-shaped mass with perfectly smooth edges. Very soon segmentation was seen again and the haustral markings showed. He continued the observation for some time, during which the transverse colon remained empty. In another case, the ascending and descending colon being filled before the observation, he observed the contents of the ascending colon suddenly pass into the transverse colon and remain there. Basing his theory upon these observations, Holzknecht declared that the movement of large intestinal contents in this manner occurred three or four times daily, at perhaps eight-hour intervals, each movement occurring within a few seconds. Observations on these movements have also been published by Schwarz,[9] Barclay,[7] Stierlin,[8] and myself.[11]

Fig. 9.—This case illustrates the large pendulum movements of Rieder.

Within the last sixteen months I have observed in thirty-seven different individuals mass peristalsis following a bismuth meal, as first described by Holzknecht. I have seen a similar phenomenon in numerous unrecorded cases following bismuth injection of the colon. The majority of them have been observed in the transverse and descending colon. The bowel contents suddenly lose their haustral markings and are formed into an ovoid, sausage-shaped mass, with perfectly smooth edges and rounded at the ends. This mass travels at about twice the rate of peristaltic waves in the stomach. In the appendix to this paper will be found a description of a number of instances of mass peristalsis. After the mass comes to rest the haustral indentations reappear, the time required for the reappearance depending upon the consistency of the bowel content—quickly if the content be semi-fluid, more slowly if the bowel content is of a firmer consistency. (See Figs. 4, 5, 6, 7.)

In connection with my various observations on colon peristalsis I have dictated careful notes to a stenographer either during the occurence of the mass movement or immediately afterwards. I have carefully studied and compared the memoranda made in each of these cases with reference to the taking of a meal, the occurence of massage, electrical treatments, the drinking of cold water, manipulation under the fluorescent screen, previous movement of the bowels, etc., and it has seemed to me that the most constant artificial factor which might be considered as bearing a causative relation to mass peristaltic movements has been manipulation of the colon through the abdominal wall. This has occurred as kneading of the abdomen or of the colon intended as a definite massage treatment or as manipulation in connection with the examination.

The immediate effect of massage and mechanical vibration has been carefully studied under the fluorescent screen. (See the detailed case reports below.) The immediate effects observed have been a deepening of the haustral contractions and sometimes the appearance of antiperistaltic waves. On only one occasion have I been able by any mechanical manipulations to produce a visible movement of the colonic contents distalwards. On one occasion I was able to move a bolus of bismuth from the cecum through the gas-filled ascending colon to the hepatic flexure. The well-recognized favorable influence of massage and mechanical vibration must therefore be produced indirectly through increasing the tone of the bowel muscle, rather than through any actual mechanical pressure of the bowel contents onward.

To determine the influence of electrical stimulation a patient was given a silk string seven meters long, one end of which he swallowed. At the end

Fig. 10.—A case of ileocolic valve incompetency of rather marked degree.

of twelve hours the string had traversed the entire gastrointestinal tract. A special olive-tipped bougie, kindly loaned me by Dr. M. M. Portis, Chicago, was then threaded over the distal end of the string and passed up the colon as far as the splenic

flexure. Although repeated efforts were made to pass the electrode around the splenic flexure I did not succeed, the flexure being very sharp in this case. A litre of a gummy suspension of bismuth oxychloride in water was then injected, filling the

Fig. 11.—An unusually marked case of ileocolic valve incompetency. This patient was examined once a month for five months and the same degree of incompetency was found at all examinations.

colon throughout. Faradic, sinusoidal and interrupted galvanic stimulation was then applied, the olive-tipped bougie serving as one electrode and a pad upon the lower abdomen completing the circuit. Although careful and repeated observations were made no actual contraction of the muscle coat of the bowel was recognized. One must conclude, therefore, that electrical stimulation with a unipolar electrode within the bowel does not suffice to produce actual contraction of the bowel wall.

J. H. Kellogg[21] has secured excellent clinical results by stimulating the pelvic colon by means of a bipolar electrode which was used with the idea that a tonic constriction ring might be formed which would give rise to peristaltic waves, thus aiding in overcoming constipation, due to inertia of the lower bowel. This condition must be particularly common in persons suffering from chronic constipation.

In a future communication I shall report the results of experiments to test radiologically the effect of a bipolar electrode high up in the colon in an effort to produce a tonic constriction ring in the transverse colon.

Braam-Houckgeest[22] suggested that these movements were stimulated by the passage of strongly acid food from the small intestine into the cecum. These movements are often accompanied by gurgling sounds, the so-called borborygmi. Nothnagel[23] believes that these movements approach the pathological. That these large, stormy movements are frequently seen in pathological cases there is no doubt. The diarrheal cramps of man are often accompanied by these large peristaltic waves. Nevertheless, in many cases subjective sensations during the progress of the mass movements are not recognized by the patient.

It may be inferred from the evidence before us that the large colon movements have a relation to bowel evacuation. They are regularly seen before or during bowel evacuation, but, as has been shown by Rieder and Schwarz, they are not necessarily associated with the emptying of the bowel. It appears that these mass movements are the chief means by which food progresses along the colon.

The above remarks have all had reference to observations made after the *ingestion* of bismuth. Following the bismuth clysma, one frequently sees a large ring constriction passing along the colon distalwards. (Fig. 8.) Whether or not the ring constriction appears depends upon the tonus of the bowel. In cases of spasticity, a relatively small enema will suffice to evoke these ring constrictions which in speed and depth resemble the mass movements first described by Holzknecht and are probably identical with them. These waves are definitely the result of distention. They have been seen to begin in many cases at the junction of the cecum and ascending colon, opposite the ileocecal valve. Often the cecum itself has been seen to be emptied. In every case in which these peristaltic waves have been seen to begin not at the tip of the cecum, but at the level of the ileocecal valve (operative proof furnished later) the cecum and appendix have been found involved in adhesions. In other words, I believe we may conclude that when these ring constrictions, the result of over-distention of the bowel, persistently fail to empty the tip of the cecum, it may be inferred that the cecum is fixed by adhesions, frequently associated with appendix disease. This finding suggests that it is the fixed rather than the freely movable cecum, which is likely to give rise to stasis and it would indicate

Fig. 12.—Marked ileocolic valve incompetency *with dilatation* of the terminal ileum.

that undue importance has been attached to the condition known as mobile cecum; that adhesions and fixation of the cecum, rather than excessive mobility, are likely to give rise to evil consequences, and that possibly harm, rather than good may be done

by operations for fixation of the cecum. These ring constrictions have been seen to traverse the bowel from the cecum to the middle of the descending colon and are usually accompanied by subjective sensations on the part of the patient, varying from a mild distress to painful cramps.

*Haustral Churning.*—Haustral churning is believed to occur in the distal colon constantly, serving to maintain plasticity of the material in this region and thus assist in its progress along the colon. I have nothing new to add concerning this form of colonic activity, although I have almost daily confirmation of its existence.

The "large pendulum" movements described by Rieder I believe are the precursors of the mass movements just discussed. These large, churning movements, the forerunners of the large peristaltic waves, are well illustrated in Figure 9. They have been seen in the transverse, descending, and pelvic colon and were followed, in nearly every instance, by a mass movement.

*Ileocolic Valve Incompetency.*—I have for a number of years observed incompetence of the ileocolic valve in a certain percentage of cases. Looking back over my statistics, I find this percentage very constant. Before the American Roentgen Ray Society in September, 1912,[11] I reported that out of a series of two hundred gastrointestinal cases referred for Roentgen examination, thirty-three, or one in six, showed incompetency of the ileocolic valve, as determined by the barium clysma. I am now able to report two hundred and fifty cases of ileocolic valve incompetency out of a larger series of about fifteen hundred individuals.

Through the courtesy of Dozent Dr. Holzknecht I had the pleasure of demonstrating several roentgenograms of incompetency of the ileocolic valve before the Gessellschaft für innere Medizin, Vienna, November, 1914.[24] At the time, I also had the pleasure of demonstrating my method of testing the competency of the ileocolic valve in the Roentgen clinic of Dr. Gottwald Schwarz, attached to the service of Professor von Noorden. I also gave a demonstration of stereoroentgenograms before the Royal Society of Medicine in London, Electrotherapeutic Section, January 19, 1912.[25] (See figures 10-12.)

Kraus[26] found in 150 autopsies after death from all causes, 12 cases of incompetency of the ileocolic valve. Singer and Holzknecht[27] remarked upon the relative frequency of insufficiency of the ileocolic valve, 3 out of 15 cases examined by clysma presenting this condition. Haenisch[28] calls attention to the frequency of this condition. Groedel[29] has reported on the pathological changes in the region of the ileocolic valve in cases of ileal stasis, believing that the incompetency is often due to chronic perityphlitis.

I am now able to report that in my much more extensive series of cases (1,500) in each of which the competency of the ileocolic valve was tested by the bismuth enema, I have found incompetency of the valve in nearly 250 cases, or 1 in 6, the same proportion observed in the smaller series first reported. It should be noted that since these were gastrointestinal cases referred for bismuth meal examination, including cases of suspected gastric carcinoma, gastric ulcer, duodenal lesions, gallbladder disease, chronic appendical disease with or without fixation of the cecum, kinks, torsions, spasms, and tumors of the colon, the presence of ileocolic valve incompetency might be expected in a relatively large proportion of cases. Since the importance of ileocolic valve incompetency has been recognized and its symptoms more definitely studied, a number of cases have been clinically diagnosed by my colleagues as ileocolic valve incompetency and the patients have been referred for roentgenographic study with special reference to this point.

Determination of ileocolic valve incompetency is surely a matter of considerable importance. It is generally agreed among anatomists and physiologists that the valve is normally competent, both to gas and fluid. The proof of the existence of antiperistalsis, especially the proof that it occurs in man, increases the probability that the ileocolic valve should be competent under normal conditions.

The observations of Kellogg and other surgeons during various abdominal operations, gives abundant confirmation of my belief that the normal ileocolic valve is thoroughly competent.

I have found the ileocolic valve of the pig and the dog competent, withstanding enormous gas or fluid distention of the colon.

The following surgical operation on a dog is further proof of the competency of the normal ileocolic valve. In a dog, the pelvic colon was divided. The ileum was also divided about 10 inches from the ileocolic valve. The proximal end of the divided ileum was inserted into the proximal end of the divided pelvic colon, the distal end of the ileum and the distal end of the pelvic colon being joined. Thus the course of the food was from the ileum into the descending colon, then into the transverse, the ascending, through the ileocolic valve, and the last 10 inches of ileum, into the pelvic colon and rectum. The dog died of intestinal obstruction 36 hours later, the intestinal contents having accumulated on the distal side of the ileocolic valve which had remained thoroughly competent.*

Bull[20] stated in 1878 that one liter of water injected into the bowel was sufficient to reach the cecum. Bull's experiments convinced him that in the living body fluid could not be forced beyond the ileocolic valve, but when the bowel was distended by air, the valve was rendered incompetent and air entered the small intestine.

Dawson,[21] in 1885, after experiments upon the cadaver, concluded that the ileocolic valve, when normal, effectually guards the small intestine from gas and fluid from below.

Ziemssen[22] recommended inflation of the rectum as a means of diagnosis and treatment *by special procedure*, the patient being placed under anesthesia. He states that as a rule, the small intestine is usually closed to the return of material from the colon into the ileum by the ileocolic valve. Under deep chloroform anesthesia, however, this resistance is decreased and fluid can be forced into the small intestine. Heschl,[23] after a number of experiments, concluded that the ileocolic valve acts as a safe and sufficient barrier to the entrance of fluids from the colon into the ileum.

On the other hand, Cantani[24] firmly believed that the ileocolic valve was permeable to fluid injection and suggested that the small intestinal tract be utilized in cases of rectal alimentation and in cases requiring the use of medicinal enemata. In one instance, he treated a case of bowel obstruction by the injection of oil. Half an hour later, part of the oil was vomited.

*The operation on this dog was kindly done by Dr. D. B. Phemister.

Battey[35] was convinced from clinical experience that the whole alimentary tract was permeable to the enema.

Illoway[36] reports four cases of intestinal obstruction treated by forcing water beyond the ileocolic valve. Three of these cases recovered.

Senn,[37] in discussing the use of the rectal injection in overcoming bowel obstruction due to invagination, states that when the obstruction is located beyond the ileocolic valve, no reliance can be placed upon this method.

Senn based this theory upon the following experiments:

"While completely under the influence of ether, the abdomen of a cat was opened and an incision was made into the ileum just above the valve. By gently retracting the margins of the wound, the valve could be distinctly seen. Water was then injected per rectum and after the cecum became well distended it could be readily seen that the valve became tense and appeared like a circular curtain, preventing effectually the escape of even a drop of fluid into the ileum. The competency of the valve was then overcome by overdistention of the cecum, which mechanically separated its margins, allowing a fine stream of water to escape into the ileum. The incompetency of the valve was clearly caused by the great distention of the cecum. That such a degree of overdistention is dangerous is proved by this experiment, as the cat was immediately killed, and examination of the colon and rectum showed a number of longitudinal rents of the peritoneal coat."

In another experiment, a cat was etherized, and while the body was inverted water was injected per rectum in sufficient quantity and with adequate force by means of an elastic syringe to overcome the resistance offered by the ileocolic valve. After the competency of the valve was overcome, the water rushed through the small intestine, traversed the entire alimentary tract, and issued from the mouth. About a quart of water was forced through the valve in this manner. The cat was killed and on examination two longitudinal lacerations of the peritoneal coat of the bowel over an inch in length on opposite sides of the bowel were found.

In experiments in which fluid was forced beyond the ileocolic valve, post-mortem examination revealed in two cases longitudinal lacerations of the muscular coat of the rectum. A third animal died immediately after the experiment, from the effects of the injection. "The forcible injection of water beyond the ileocolic valve must therefore be recognized as a dangerous expedient and should never be resorted to." (Senn.)

However, Senn states that under normal conditions, the ileocolic valve in a healthy adult person is overcome by rectal inflation under a pressure of 1½ to 2¼ pounds (0.7 to 1.1 kilo), and that this amount of pressure is not sufficient to injure the tunics of the intestine. The inflation should be made slowly and steadily to avoid injuring the intestine. It requires a pressure of only 1 to 2½ pounds (0.4 to 1.1 kilo) to force air through the ileocolic valve and out of the mouth, while even the weakest portion of the gastrointestinal tract effectually resists a pressure of 8 to 10 pounds (3.6 to 4.5 kilo). The experiments of Behrens[38] agree with those of Senn.

According to Senn, the escape of air through the ileocolic valve from below upward is attended by a blowing or gurgling sound heard most distinctly over the ileocecal region and by a sudden diminution of pressure. The incompetency of the valve is caused by a lateral and longitudinal distention of the cecum, which mechanically separates the margins of the valve.

Débièrre[39] experimented on the cadaver and found the valve more often permeable in cases where the lower lip was smaller, contracted and shorter than the upper. If both lips of the valve were equal in length, the valve was usually impermeable.

Piersoll[40] calls attention to the fact that under anesthesia the tonicity of the muscular fibers of the gut is less and in the open abdomen the pressure of the viscera on the end of the ileum is less than normal. Hence, if the experiments are performed *in situ*, the closure is more likely to be perfect than if the parts have been lifted out of the abdomen.

In 35 or 40 individuals, I have examined the ileocolic valve on more than one occasion to determine whether or not the competency observed was transient or whether it was permanent. In some cases, the patients have been examined a third time. The interval between the two examinations in several instances was as long as three months. Without exception, when the ileocolic valve has been found incompetent to the bismuth enema on one occasion, it has been found incompetent on all examinations. In one patient in particular (Fig. 11) who was examined once a month for five months, the ileocolic valve was found incompetent at all examinations and the degree of filling of the ileum was approximately the same on all five occasions.

A very strong evidence in favor of the normal competency of the ileocolic valve is the fact that when incompetent, its competency may be restored by a simple surgical procedure. Dr. J. H. Kellogg, chief surgeon of the Battle Creek Sanitarium, whose interest in this matter was enlisted through the great frequency with which I was discovering incompetency of the ileocolic valve in the course of my routine bismuth examination work, agreeing in the belief that the ileocolic valve incompetency must be an important factor in the production of intestinal stasis, has devised an operation for restoring the competency of the ileocolic valve which he has performed in more than 30 cases.[41] In every single case, the Roentgen diagnosis of the ilecoceal valve incompetency was confirmed at operation and that the valve competency was restored by the operation performed was determined not only by testing the valve *in situ*, before the abdomen was closed, but by later roentgenographic tests. In every single case, the barium clysma test has later proved the competency of the valve. The influence of this operation upon the emptying time of the ileum has also been tested by the usual bismuth meal. Thus far no evidence has been secured which would lead us to believe that there has been the slightest hindrance to the passage of ingested food from the ileum into the colon. On the contrary, the length of time required for the ileum to empty has been distinctly shorter than before the operation, more nearly approaching the normal. It should be remarked that the operation for repair of the ileocolic valve was, in each of the cases above referred to, performed in connection with some other operation requiring opening of the abdominal cavity. As stated by Dr. Kellogg in a recent paper,[42] he is firmly convinced that in certain cases it may be perfectly justifiable to operate definitely to restore the competency of the ileocolic valve. In a few instances in which the ileocolic valve had appeared to be competent to the bismuth enema, at subsequent operation, the competency of the valve appeared to be open to question, at least in relation to gas, since slight pressure upon the cecum was found sufficient to cause a reflux into the ileum, after the latter had been thoroughly emptied. In accounting for such cases, I have borne in mind the experimental evi-

dence above quoted that under anesthesia the tonicity of the muscular fibers of the gut is less and have assumed that the valve itself was incompetent even at the time of the bismuth enema, but with the patient awake and the bowel tone normal, the activity of the ileocolic sphincter was sufficient to prevent a reflux of the clysma into the small intestine, even though the valve lips did not closely approximate. It should be further noted that at operation, the test of the valve competency is made with gas and not with fluid. The experiments of Senn and others would indicate that one may overcome the competency of the ileocolic valve much more easily with air than when employing fluid, especially with the patient under anesthesia.

A case of special interest is that of the young man above mentioned into whose gastrointestinal tract I introduced a silken thread, 7 meters long, traversing the entire length of the tract. I tested the ileocolic valve competency on two separate occasions before introducing the thread, and again after the thread was in place and found that the valve was still thoroughly competent. Then using the thread as a guide, I introduced a metal electrode as far as the upper end of the descending colon, incidentally making more or less traction upon the thread in the effort to pass the sound around the splenic flexure. The traction upon the thread rendered it taut in the region of the valve, producing an incompetency as demonstrated by roentgenograms made a few moments later, showing the terminal ileum filled for a considerable distance. After the experiment was concluded and the thread withdrawn, another examination was made and the valve again found to be normally competent.

It is frequently stated in literature with reference to rectal alimentation that if the nutriment be given in saline solution, it is more likely to be carried past the valve. In order to test this point, in a series of 50 colon injections, I added enough salt to the clysma to give it the strength of normal saline solution. Comparing these 50 consecutive cases with the preceding 50 and the 50 succeeding colon injections made without salt, I was unable to see the slightest difference in the percentage of ileocolic valve incompetencies.

I also made several series of experiments to test the influence of the composition of the bismuth clysma. I found that using barium sulphate, bismuth oxychloride or bismuth subcarbonate in a gummy suspension in water with or without saline solution and in buttermilk suspension with or without the addition of salt, I obtained constant results, the same percentage of cases, one in six, holding practically constant.

In reviewing the notes of my large series of cases of ileocolic valve incompetency, the most striking fact learned is that, in the majority of cases, ileocolic valve insufficiency is associated, not with diarrhea, but with constipation. Our present knowledge of the antiperistaltic phenomena in the colon makes it easy to understand why we find ileal stasis and constipation rather than hypermotility, when reflux from the colon into the ileum is no longer prevented by a competent ileocecal valve.

A discussion of the clinical symptoms and pathology of the ileocolic valve would not be in place in this paper. The clinical aspect of this subject has been fully discussed by J. H. Kellogg.[42]

It is generally recognized that rectal alimentation is, on the whole, unsatisfactory, although there are enough cases of successful rectal alimentation to warrant the continuance of the practice. In the light of our present knowledge concerning the ileocolic valve incompetence, it seems to me reasonable to believe that those cases in which rectal alimentation has proved successful were cases of ileocolic valve incompetence. Under ordinary conditions the valve acts as a sufficient barrier so that any attempts, either for diagnostic or therapeutic use to introduce fluid beyond the ileocolic valve are unsafe and unjustifiable.

In the text I have recorded several of the observations upon which this paper is based. I will close by appending the observation notes in a few interesting cases, which were dictated to a stenographer as the patients were being examined. Space permits the publication of only a few of the 67 very interesting observations thus recorded.

## OBSERVATION NOTES.

Case IX.—(Miss I. C.) Observation at 9:30 A. M., fifty-two hours after the Rieder meal. It was seen that the colon was well filled from cecum to splenic flexure, the first half of the colon being well filled. It was also noticed that there was in the pelvic colon near the rectum a bolus of bismuth having the appearance of having just come to rest after a mass peristalsis. The edges were smooth and the shadow was regular and round, the size of a hen's egg. I noticed this mass in the pelvis making an onward movement, which excited my interest. The transverse colon was so prolapsed that it hung down over the pelvic colon, so I manipulated with my hand in order to displace it upward. Immediately after my manipulations I saw the bismuth occupying the middle of the transverse colon suddenly lose its haustral markings and bunch up into a mass, the size and shape of a small banana. This at once started on its way toward the splenic flexure. The distal end of the mass was broader and tapered off toward the proximal end. Its progress was about twice as rapid as a peristaltic wave in the stomach or perhaps a little faster. The onward progress of this mass is illustrated in Figs. 7, 8, 9. About half of it was left in the descending colon. The remainder went on into the pelvic colon and was added to the mass already there, above referred to. After this there was a slight movement of smaller masses, but no other large mass movement. The patient said she had no sensation that there was peristalsis in progress. She did not have any desire to defecate. The patient had a glass of water with breakfast, but no water since. Observation at 9:30; breakfast at 7:30; no bowel movement. The patient has always been constipated. She stated she did not think the bowels moved three times in the past year without assistance.

Case XV.—(Mrs. N. W.) At the eleventh hour, bismuth was seen evenly distributed throughout the cecum, ascending, and transverse colon. I made considerable manipulation of the cecum to determine the presence of the bismuth shadow in the appendix and to test the mobility of the cecum. I also made manipulations to separate the two legs of the hepatic loop. Just as I was about to close the examination I caught a glimpse of a blotchy, sausage-shaped shadow, which told me either of an impending mass movement or one just at an end. In this case it proved to be one just ending, bismuth having been carried from the cecum around the hepatic flexure into the first part of the transverse colon. The borders of the mass were still perfectly rounded and smooth. During further observation the contraction of the circular muscles slowly and increasingly indented this shapeless mass until it took on the appearance of haustral segmentation. The appearance of the rest of the bowel showed a state of peristaltic unrest—the large, pendulum movements of Rieder. In at least two places, a small sausage-shaped mass was in motion at about the same rate as peristaltic waves in the stomach. It seemed that respiratory movements aided in the onward progress of the small bismuth masses. Manual vibration was then made over the cecal shadow in the effort to stimulate another large peristaltic movement, but instead of producing an onward wave distinct antiperistalsis was observed. The haustral indentations became deeper. During the next half hour a number of observations were made, showing clearly that peristalsis and antiperistalsis were occurring in the right half of the colon. It was also seen

that the pelvic colon was gradually filling up, small boluses the size of a pigeon's egg traveling slowly down the descending colon into the pelvic colon. Mechanical vibration was then employed, first over the cecum and then over the whole of the ascending and transverse colon. The only observable result was an increase in the depth of the haustral segmentation and a general, more even distribution of the contents of the colon throughout its entire extent. In this case there was a persistent constriction at about the junction of the right and middle thirds of the transverse colon. This constriction was seen at nearly all observations, although occasionally it relaxed, but then only for a short length of time.

Case XXII.—(M. V. S.) At the observation made twelve hours p. c., the same appearance of bismuth figure, as heretofore described, was noticed. In this case a sausage-shaped mass occupied the first part of the descending colon. The head of the bismuth column reached within three inches of the crest of the left ilium. During the observation, which lasted fifty minutes, the head of this bismuth column traveled at least seven inches. At no time could I say that I saw an actual movement of the bismuth except that caused by respiration. The movement was quite imperceptible, yet observations made from time to time at intervals of three or four minutes showed the unmistakable onward progress. After ten or fifteen minutes a small bolus of bismuth the size of a filbert was separated from the head of the bismuth column, and during one of the intervals between observations was carried from the level of the crest of the ilium clear down into the pelvic colon. The bismuth in the region of the hepatic flexure also exhibited active antiperistalsis, definite waves being seen in the first two or three inches of the transverse colon. In this instance, following the above observation, careful massage was given very thoroughly, the masseur having first carefully noted under the screen the position of the transverse colon. Massage was given under the most favorable circumstances possible, but aside from the increased depth of the haustral markings no appreciable change could be noticed during five minutes. Following the massage, antiperistaltic waves were observed.

Case XXXI.—(Mrs. J. M.) When examined twenty-two hours p. c. the appendix region was carefully searched and the cecum palpated to determine its mobility, after which I glanced at the rest of the colon to determine the extent of filling. It was seen that the bismuth filled the transverse colon and onward as far as the middle of the descending colon. Further search, accompanied by manipulations, was made in the region of the cecum, after which the diaphragm was opened for a final look at the whole abdomen before closing the observation. At this time my attention was attracted by the peculiar configuration of the contents of the descending colon. The haustral indentations were no longer present. A large segment of the bowel contents, probably five inches in extent, was pinched off by a single contraction, very similar to that seen in the stomach. While observing, this ring contraction was seen to pass at about twice the rate of peristaltic waves in the stomach, distalwards, carrying before it this large mass of bowel contents, five inches in length. The bowel behind the peristaltic wave was left empty except for a faint trace of the bismuth leaving a shadow about the size of a small lead pencil from the splenic flexure downward. This wave traveled from the splenic flexure to the iliopelvic junction without hindrance. While making further examination a second collection of bismuth, about four or five inches in length was seen to round the splenic curve on its way downward. The patient stated that just before the observation she had had an inclination to empty the bowel. The observations were made three hours after breakfast. Just before coming into the examining room the patient drank one glass of cold water.

Case XL.—(Mrs. D.) Observation twelve hours p. c. I noted that the bowel presented the appearance of peristaltic unrest (Fig. 9), characterized by Rieder as the large pendulum movements. The head of the bismuth column had reached the middle of the descending colon. The cecum was in normal position and not unusually large. The terminal ileum was filled by a considerable mass of bismuth, evidently a case of ileal stasis. I had the patient drink a glass of cold water, after which thorough colon massage was administered. The massage appeared to have a most pronounced effect in emptying the terminal ileum. I then observed once more the position of the head of the bismuth column and it was seen to have moved onward at least five inches in the descending colon. During this study, although a number of observations were made during the course of the massage, I did not at any time see the mass actually move, but from the observations it was evident that the head of the bismuth column was moving onward. In the first part of the transverse colon an isolated mass of bismuth was seen to move backward toward the cecum, showing definitely the presence of antiperistalsis.

Case XLIV.—(Mrs. M. C.) Observation twelve hours p. c. On beginning the observation bismuth was seen in the terminal ileum and in the colon from the cecum to the first third of the transverse. I manipulated the cecal region for a few moments, using the Holzknecht palpatorium. My attention was diverted for a moment and when I again illuminated the screen I saw that the cecum and ascending colon were empty and that there was a large, smooth-bordered collection of bismuth occupying the right half of the transverse colon at about its middle. A large bolus about four inches in length and one and a half inches in diameter, rounded at the ends, was separated off and carried across the transverse colon, down the descending, into the iliac colon. Twenty minutes later the patient was again observed and it was noted that the colon was uniformly filled from the cecum to the middle of the descending colon. A very thorough, carefully directed massage was then administered in this case to induce, if possible, another mass movement. No portion of the bismuth was disturbed by the massage, but, as previously observed, the haustral indentations became more pronounced during the last fifteen minutes. The sausage-shaped mass which had been carried from the hepatic flexure into the descending colon made no further progress.

Case LVII.—(Mrs. M. B.) Observation twenty-eight hours p. c. The patient had a chronic duodenal ulcer with marked gastrectasis. At the twenty-eighth hour there was still a considerable residue in the stomach. The entire colon was seen to be filled from cecum to rectum, the shadow being of small caliber and not very dense, especially in the pelvic colon. The cecum was manipulated to study the appendix and test its mobility, but the appendix was not visible. I then glanced at the stomach to study the pylorus further. My eye was caught by the characteristic blotchy shadow in the ascending colon, indicating an impending or just ending mass movement. In this instance the bismuth was seen to move rapidly onward through the entire length of the prolapsed transverse colon at, at least, twice or three times the rate of speed of peristaltic waves in the stomach. This bolus of bismuth was seen to pass into the very rectum itself, having originated in the hepatic region.

Case LX.—(Mrs. A. J.) Observation ten hours p. c. The colon was seen to be filled as far as the middle of the transverse colon. The bismuth collection looked suspicious of peristaltic unrest and at once aroused my attention. While observing a bismuth mass the size of a small lemon was moved backward half way around the hepatic flexure. This observation had been preceded a few moments before by manipulation of the cecum and ascending colon. While watching for still further movement, this bolus of bismuth was seen to travel clear across the transverse colon and down into the sigmoid. During the first part of the observation the progress of the bismuth cecalward and the reversion in the direction of the bolus toward the sigmoid took place at about the same rate as peristalsis in the stomach. After that the progress was slow and could only be noted by observation from time to time. At the twenty-eighth hour the patient reported a copious bowel movement, a rather unusual occurrence with her.

Case LXII.—(Mr. S.) Observation following bismuth injection. Normal filling of the colon. Ileocecal valve competence. Following the injection, the patient was able to empty the colon completely except for a bolus of bismuth in the cecum the size of a goose egg. For perhaps two minutes my attention was diverted, after which the observation was renewed. There was at once observed the characteristic, smooth-edged, blotchy appearance of the bismuth shadow which means an impending or just ending large pendulum movement. The shadow was smooth-edged and was clearly cut off at both ends except for a track (trail) of bismuth on the proximal side. This bismuth bolus traveled from cecum to iliac colon in one rapid peristaltic movement, less than two minutes being required to traverse the entire distance. A retrograde movement was observed in this case, a bismuth bolus traveling from the iliac

colon back to the splenic flexure, after which it flattened out and the haustral markings began to show. The bolus became progressively thinner and longer.

CASE LXVI.—(H. R. T.) Observation ten hours p. c. Bismuth still showed in the small intestine for about four inches. The appendix was visible. The cecum was freely movable. The head of the bismuth column reached as far as the last third of the transverse. The cecum was manipulated considerably. Shortly afterwards there was a mass movement in the left third of the transverse colon, carrying a bolus into the descending colon down as low as the crest of the ilium, where it soon again took on its haustral markings.

# A SIMPLE SUBCUTANEOUS CUT TO CURE "TRIGGER-FINGER" OR "SNAP-FINGER."

BY ROBERT ABBE, M.D.,
NEW YORK.
SURGEON TO ST. LUKE'S HOSPITAL.

MOST physicians have occasionally encountered a case of trigger-finger and have been puzzled to account for its cause, or to cure it.

The patient grasps a brush, or closes the finger over any medium sized object, and on releasing it, finds the little finger or one of the others refuses to open. The victim uses his other hand to raise the finger, when it suddenly jumps up with a snap and sometimes a little pain.

This has been variously explained by surgeons of many countries as due to a supposed swelling, due to a congested point somewhere along the flexor tendon where it catches under a restricting bridge of fascia covering the tendon sheath. This tumefaction has not been well demonstrated or uniformly located at any point. My first five cases reported assumed this explanation.[1] After studying many subsequent cases[2] I operated at last on the annoying case in the hand of my revered master in surgery, Dr. Robert F. Weir.

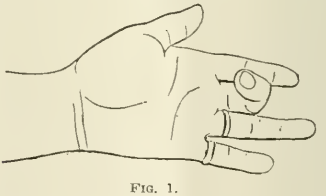

FIG. 1.

He wrote extensively of this topic in reporting his own case.[3]

I operated under cocaine anesthesia by a long incision beginning near the distal joint of his finger, finding no relief to the repeated snapping tests with the tendon exposed in the open wound until I had cut nearly to the middle of the palm. Then, by division of the constricting transverse fibers resting on the tendon sheath, the relief was instant and has endured for years.

I then decided to try a simple subcutaneous cut with a fine knife at this point in the next case pre-

senting itself for my care. I located this bridge *exactly under the extreme flexure crease of the palm.*

Recently a distinguished artist sought relief from this distressing condition. He had been

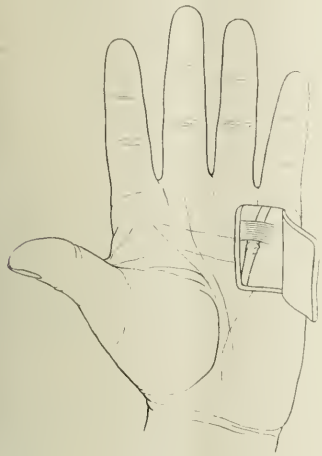

FIG. 2.

obliged to paint with his palette on a table, because when holding it and his brushes in the grasp of his left hand, the little finger stuck tight down and only admitted relief with a painful snap. I at once painted the part with iodine, inserted a fine bistoury in the flexure crease, and pressing the point down to the tendon, drew it along for a half inch. The relief was instantaneous and final. The finger now closed into the palm and played naturally without catching. A small pad of boracic gauze made pressure for two days and the trouble was cured.

The tendon is easily located by thumb pressure at the crease, and is not covered by nerve or vessel. Cutting the tendon fibers lengthwise (if one wished to cut deeply, which is not necessary) would in no wise damage the tendon.

I offer this as the simplest and most perfect operation for the cure of this distressing condition.

The trouble is explained, not by a rheumatic tumefaction of the tendon, but by a crumpling up of the conjoined flexor tendon at the point indicated in the drawing, very much as a tape might crinkle when slack, above a slot and refuse to pull back easily.

This simple operation not only solves the riddle but cures the malady.

**A Case of Jaw-Winking.**—F. G. Crookshank reports the case of a girl, aged nine years, who had congenital unilateral ptosis. When the muscles of her face were at rest this ptosis was considerable. When she depressed her jaw or moved it sideways, not only did the ptosis disappear, but the sclerotic became visible on the affected side, above the cornea.—*Proceedings of the Royal Society of Medicine.*

# A CAUSE OF PERITONEAL ADHESIONS IN A NEW BACILLUS; THE BACILLUS ADHÆSIOFORMIS.

BY ANTHONY BASSLER, M.D.,

NEW YORK.

PROFESSOR OF CLINICAL MEDICINE, NEW YORK POLYCLINIC MEDICAL SCHOOL AND HOSPITAL; VISITING PHYSICIAN, NEW YORK POLYCLINIC HOSPITAL; CHIEF GASTROENTEROLOGIST, GERMAN POLIKLINIK; VISITING GASTROENTEROLOGIST, PEOPLE'S HOSPITAL; CONSULTING PHYSICIAN, BETH-DAVID HOSPITAL

THE right half of the abdomen is peculiarly liable to perienteric adhesions. Most of these are found from the lower end of the ileum to the sigmoid, mainly, the ascending colon, hepatic flexure, and the right half of the transverse colon. They are also found in the stomach, duodenum, and gall-bladder. The terms "pseudo-peritoneal adhesions," "Jackson's membrane," "Lane's kink," "gallspider adhesions," "membranous periocolitis," and "membranous perienteritis" seem part of a same process, namely, a reaction on the part of the parietal peritoneum to irritation, protection from irritation, or both. Frank irritation is seen in the posterior adhesions of the cecum and ascending colon in the agglutinizing form and the anterior fan-like adhesions of firm consistency that pass directly from the gut to the parietal peritoneum or to other portions of the gut; protection against the production of such stiffer and thicker adhesions is seen in the formation of the pseudoperitoneal membrane which Jackson described in 1909.

The etiology of the production of these adhesions is held by many as not yet settled. Some believe that they are non-inflammatory, among these, Lane and Mayo; the former, that they are secondary to enteroptosia with chronic constipation, and the latter, that they are a congenital condition. Leander

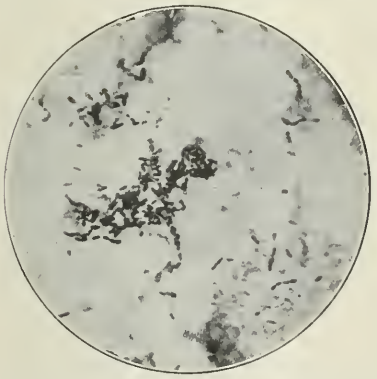

FIG. 1.—Case I. Photomicrograph of the bacteria. Gram differential stain, not counterstained so that only the Gram positives are visible. X 1000. At each of three operations performed for obstruction due to adhesions it was noted that, beginning with them only at the sigmoid, they successively involved the descending colon, the splenic flexure, the ascending colon and the cecum, and finally the lower ileum. The operations were performed each time for a slowly developing stenosis at one of these sites, the intestine having become impassable. At present there is definite stenosis at the sigmoid, splenic flexure, ascending colon, and the lower ileum. The adhesions are fibrous in type. (Patient, Dr. G. A. S. Referred by Dr. Robert T. Morris.)

believed them due to colitis in infancy, and Binnie and others that they are secondary to chronic colitis. Recently, suggestive argument has been advanced that they mostly are secondary to certain unknown toxic processes primarily taking place

within the gut. The study of the bacteriology of stools in my cases, and the findings at operation and postmortem at which the parts are visually examined and the contents of the gut studied bacteriologically, prove to me that they

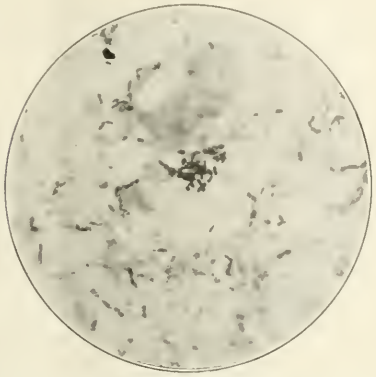

Fig. 2.—Case IX. Same bacteria as Fig. 1. At operation, Lane's Kink; extensive Jackson's membrane generally involving the right abdomen from the lower cecum to the proximal transverse colon; chronic appendicitis and several bands of perienteric adhesions. (Patient, A. G. Referred by Dr. Francis P. Kinnicutt.)

are commonly due to changes in the bacteriology of the intestinal canal in its most active part, namely, from the lower ileum to the mid-transverse colon, and that the resulting adhesions are reactions of the peritoneum from bacteria-food toxins resorbed by the lymphatics and venous radicals as they emerge from the gut—notably those that emerge from the anterior band of the ascending colon. The event of adhesion formation in my postmortem experience may take place without evidence of ulceration or active inflammation in the gastro-intestinal tract or in other peritoneum covered viscera. It appears that a mild degree of productive fibrinous peritonitis is set up and organization of the exudate forms adhesions or a membrane according to whether the process is active or slow. When slow, time is allowed for the development of an endothelial membrane freely movable on the surface of the gut for its protection, but later on, with the persistency of the toxemia, this membrane may thicken into truer adhesions by the organization of additional tissue, these adhesions forming contracted fibrous bands. There are, however, postmortem findings suggesting that some of the adhesions are undoubtedly of frank inflammatory origin.

In the earlier stages of Jackson's membrane the colon presents a thickened or edematous appearance and, on close inspection as well as microscopic examination, the viceral peritoneum seems to be raised from the bowel-wall by reason of the presence of a subendothelial, hyaline-looking substance or exudate. This endothelial layer of the peritoneum gradually becomes separated from the bowel as a distinct layer, and beneath it, covering the bowel-wall, there forms another layer of endothelial cells. This is a protective process, but when it continues the newly formed endothelial cells on the surface of the gut are successively raised off and the process in this way forms thicker bands of adhesions, particularly when the resorption is active. The original membrane then is no longer protective, because now the adhesions are thick and firm and cannot be separated from the gut without leaving a raw and bleeding surface during life and a raw surface at post-mortem.

There is operative and post-mortem reason for the belief that this formation of membrane begins early in adult life, and very probably in the child. These are the years in which infections of the bacteriology of the intestinal canal are almost as often met with as in the older, and further than that, the process beginning in young life usually means a more virulent one, with, not only a greater liability of reaction locally, but also a more marked effect upon the system generally.

In the hope that investigation in this connection would add something to our limited knowledge of the subject, I have made studies in eleven cases that had been operated upon in which extensive colonic adhesions were observed, and seven autopsies in which various parts of the gut were carefully sectioned, in all of which the bacteriology of the contents were studied. Without going into detail of the large amount of work done, I desire to present these beliefs:

The upper part of the intestinal tract being comparatively free from microorganisms, such adhesions as are encountered in the stomach and duodenum are distinctly inflammatory in cause; those from gall-bladder infections most probably from the portal system and indirectly into the liver and toxic directly from the gall-bladder; while those from the intestines are due almost always to the resorption of soluble toxins from the site. I believe that the presence of the colon bacillus in cases of appendicitis or gall-bladder infections cannot be taken as a cause when anaerobic bacteria can always be grown from these same specimens. The colon bacillus in itself is essentially a non-pyogenic organism, and in each instance, whether it be considered responsible for an inflammation (such as in pyonephrosis, abscess of the kidney, perinephritic abscess, subphrenic abscess, and abscess of the liver) other bacteria, generally anaerobes, growing perhaps only scantily with them, are more responsible for the production of the infection than is the associated *B. coli.* The colon bacillus is symbiotic with all of the forms of intestinal anaerobes and also with most of the Gram positive saprophytes. It appears that the Welsh bacillus is the only important intestinal anaerobe capable of culturing itself easily outside of the gut. Even here, in the presence of a mixed infection, certain of the other organisms of the intestines may be found if examined for carefully.

It is known that the organisms most frequently found by the use of proper cultural methods are the anaerobes seen in all inflammatory conditions having their origin in or about the appendix. Runeberg and Heyde mention these as the *B. fusiformis* VII., *B. thetoides, B. ramosus, B. ramosoides, B. perfringes, B. butyricus, B. parapneumococcus, B. pseudotetanus,* and *B. streptococcus anaerobicus.* While these organisms, most of which are designated under other names in this country, are practically never found alone but always in symbiotic relation of two or more varieties, to which the colon bacillus and ordinary pus-producing organisms are only associates, I desire to add what I believe is an organism first described here. The various organisms mentioned are all possible of cultivation in the majority of instances having adhesions, but my investigations have led me to the belief that

neither one or any combination of them is as common a finding in these cases as the organism drawn attention to, which also is commonly associated with them.

The organism I desire to describe is a Gram positive, which may be morphologically met with in three shapes, fusiform, sausage-shaped, and a few with square ends. In raw stool specimens a few of them show a spore at one of the ends, and some show a spore at both ends. It is about as thick as the Gram positive cocci and not quite the diameter of the Gram positive diplococci. It is about half of the size of the *B. aërogenes capsulatus* and unlike that organism is not capsulated. Some of the forms, particularly those having rather square ends, are shorter and resemble those of the coccal type. Most of them have straight sides and cannot be confused with the saprophytic nodulated organisms nor the *B. putrificus* which is narrower and longer. They occur singly but are only significant in a diagnostic sense when found in groups of a dozen or more, or in great numbers; in some instances there may be as many as a hundred to a field. In every specimen they never represent the predominant organism of the stools or even those of the Gram positive forms, and are easily overlooked unless a search for them is made. When possible of being grown in culture, they never show a capsule or produce the acidity that the *B. aërogenes capsulatus* do. The fact that they have no capsule sharply distinguishes them from the Welsh bacillus in addition to the above-mentioned morphological observations, together with the fact that the Welsh bacillus is easily grown while these are not. Further than these, they are usually met with in groups and chains while the *B. aërogenes capsulatis* is usually detached except when met with in blood cultures. Further than the aforementioned, the spores of the gas bacillus are more commonly observed. A point in differentiation is that in raw stool specimens the spores may be seen while in culture specimens they are not; this suggests that they only sporulate when in the intestinal canal. If a feces extract is made to which peptone and maltose has been added they grow best, but even here with great difficulty. They are not cultivatable by ordinary laboratory methods whatever medium is used and however it is manipulated, neither by the aerobic nor the anaerobic means. Either they are mostly dead when excreted, or, like many of the other intestinal bacteria, are not cultivatable by artificial means. The bacillus is not of the colon or Gram negative group and is non-motile. It occurs in definite sizes and does not vary in size as the *B. aërogenes capsulatus* does. It resembles the *B. aërogenes capsulatus* in not possessing flagella. It is a most exacting anaerobe, decidedly more so than the *B. aërogenes capsulatus*, and in culture does not produce the amount of gas that the Welsh bacillus does.

Various media have been tried to cultivate this bacteria and all have failed but one. In two of the post-mortem specimens and one of the operative cases the bacillus isolated from the region of the head of the cecum was more possible of cultivation than that obtained from the stools. As was stated before, one can rarely grow this bacterium from the stools. There is a method, however, employed by me in studying it which answers to fair purpose, and that is to make a fluid mush of the stool in question with a normal saline solution by thoroughly macerating the stool in considerable normal saline solution. After a few hours, usually three, this fluid is centrifuged for the purpose of throwing down the solid particles of feces. The supernatant fluid is then passed through a Berkefeld filter until it is sterile of bacteria. Peptone and maltose are then added to it and the media rendered neutral in reaction with sodium carbonate. In this medium, under strictest anaerobic conditions, a sparse growth may be obtained, but no other medium, not even the Cohendy, answers the purpose. As incomplete as a Gram differential stain of raw feces is for the designation of any of the intestinal organisms, it nevertheless is the only means clinically possible here, excepting the means of the medium suggested. It must be mentioned that unless one is thoroughly familiar with the bacterial pictures of stools, other bacteria may be designated as the one drawn attention to. In my opinion, it is the most active adhesion former of any or all of the organisms known and described before, and for the purpose of advancing it still further, I have taken the liberty of giving it the clinical distinction of the name, the *B. adhæsioformis* (adhesion former.)

21 West Seventy-fourth Street.

## SPRAIN FRACTURE OF THE OS CALCIS.*

By A. O. Wilensky, M.D.,
New York.

A solution of continuity in that portion of the extensor apparatus of the foot, comprising the tendo

Fig. 1.—The plate was taken about two weeks after the injury took place. It is probable that the size of the upper fragment is much exaggerated, owing to its convexity, and to a slight formation of new bone.

*From the surgical service of the Mount Sinai Hospital Dispensary.

Achilles and the os calcis, is a fairly common injury. The line of division is most frequently present in the os calcis, through a line which crosses the point of fixation of the heel bone between the ground and the overlying astragalus. Next in order the

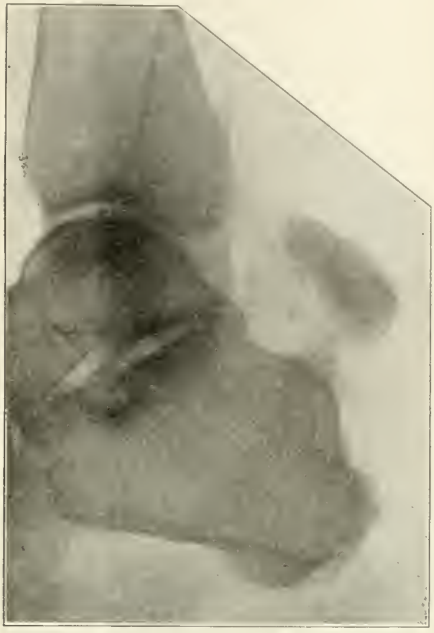

Fig. 2 shows the condition six months after the occurrence of the injury.

line of fracture will pass through the bone, between this point and the insertion of the tendo Achilles; and lastly a tearing of the tendon itself may occur.

It is uncommon for a fracture to take place, so that a thin plate of bone, corresponding to the insertion of the tendo Achilles, is torn away from the cortex of the os calcis. This would correspond to a sprain-fracture.

Case No. 971 (series of 1913).—An Irish woman, forty-two years of age, a housekeeper by occupation, fell down a short stairway into a cellar, injuring her foot. The patient is not certain as to the exact manner of falling, but remembers distinctly that the foot and leg were doubled under her. She was treated at home for about ten days, during which time she was unable to walk. When she came to the clinic she had a very pronounced limp and was unable to rise on her toes. There was marked ecchymosis, together with much edema, over the entire foot and leg as high as the knee. The *x*-ray demonstrated that a sprain-fracture had occurred, the tendo Achilles together with a thin bony segment having been torn from its attachment to the os calcis. The separation between the two torn surfaces was over an inch and there was indication that an attempt at callus formation was being made. This interval could be distinctly felt. Deformity of moderate degree was present and visible. Operation was advised, but, the patient refusing, the injured limb was treated by strapping, and by persistent massage, and passive and active motion. Two months later the patient walked with a limp, which was distinctly less than when first seen, and began to show some increase in the power of extension of the foot. She could rise on her toes, but could not maintain herself in that position. The interval between the two torn surfaces was just as large and deformity persisted, and had not grown less. There was no evidence in the *x*-ray photograph that satisfactory union by bony tissue would take place. Operation was again advised, but was refused. Four months later the patient walked with a sliding gait combined with a slight limp. She could rise on her toes more easily and could maintain that position for about one minute. The interval between the torn surfaces was filled with a hard, dense fibrous scar, and the *x*-ray substantiated that fact by showing the absence of callus formation. On the whole, it seems that the woman obtained a very satisfactory result without operation.

Fractures of the os calcis may occur by direct or indirect violence. In the former event, we have what has been called a "compression fracture." In these cases the subject usually has fallen from a great height and has landed on his heels. The os calcis is fixed between the malleoli, the astragalus, and the ground. The energy of the fall is expended directly at the point of fixation, and the fracture results. It corresponds very closely with the manner in which a stone is broken by a hammer, and the imitation is carried still further by the fact that frequently the bone is broken into more than two fragments or shows extensive comminution. In the fractures due to indirect violence, the so-called "avulsion type" of fracture, the same fixation occurs, but in attempting to prevent the injury, at the moment of falling, the patient unconsciously contracts his calf muscles so powerfully that the posterosuperior portion of the os calcis is torn away. In some cases the bone is stronger than the tendo Achilles, and the tendo Achilles itself is ruptured. This is the much more uncommon lesion. The case reported belongs somewhere between the two last conditions. It should not be considered as a fracture of the os calcis, nor as a ruptured tendo Achilles, but as a lesion intermediate between the two.

1200 Madison Avenue.

## AN APPLIANCE FOR THE INTRODUCTION OF INSTRUMENTS INTO THE STOMACH.*

By Max Einhorn, M.D.,

New York.

Professor of Medicine at the New York Postgraduate Medical School.

Several of my instruments have to be swallowed by the patient. They consist of thin, long pliable tubes, which present very little resistance and do not annoy the patient when in the digestive tract (deglutible stomach electrode, duodenal pump, etc.). Others are attached to a silk thread with the same object in view.

While in the great majority of cases there is no difficulty in their introduction, the patient usually being able to swallow them easily with water, we meet in rare instances with exceptions to this rule.

To this class of cases belong patients who never can swallow a pill or capsule, and highly neurotic individuals, who cannot apparently do what they are instructed to perform. Again, there are instances in which a cardiospasm appears and prevents the entrance of the instrument into the stomach.

Not long ago I had occasion to use the duodenal pump on a patient, and here the instrument remained probably just above the cardia for two to three days without budging, notwithstanding that the patient took liquid food and that the food entered the stomach all the time. In this patient, where the pump failed to enter in two days I introduced it into the stomach by means of the new

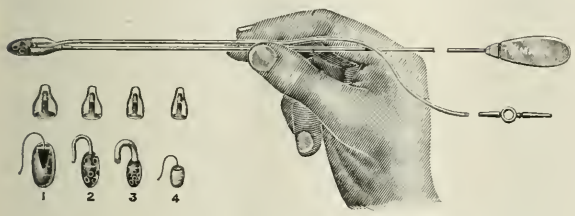
*Demonstrated at the New York County Medical Society, on January 26, 1914.

instrument—to be described in the following—in a few seconds.

To obviate just such difficulties an appliance was constructed which makes it possible to introduce the instrument desired directly into the stomach without any effort at swallowing on the part of the patient.

The instrument consists of a whalebone stem (which can be arranged in the divisible form), at the end of which is attached a hollow metal cap with a wide incision on one side and rounded off edges.

This cap fits loosely over the top of the capsule of the instrument to be introduced, the incision serving for the reception of the tube or thread attached. Caps of various sizes can be screwed on to the whalebone stem (see figure), fitting the various instruments.



The Gastric Pusher or Introducer. The top line shows the Introducer with the deglutible electrode ready for use. The middle line illustrates the different caps (1) for the stomach bucket, (2) for the deglutible electrode, (3) duodenal pump, and (4) duodenal buckets which are represented in the third line underneath their corresponding caps.

When introducing the instrument desired, the capsule top is lodged in the metal cap, and the thread or the tube of the instrument kept taut along the whalebone stem. The latter is then pushed through the throat and esophagus into the stomach of the patient. When there the tube or thread is released, the whalebone pushed a little further down, slightly shaken—this serves to separate the instrument from the cap more efficiently—and then slowly retracted. This instrument may be termed "Gastric Instrument Introducer," or "Gastric Introducer,"* or "Gastric Pusher," and can be used for the introduction of the gastric deglutible electrode, the duodenal pump, the hard rubber radium capsule, stomach bucket, duodenal bucket, etc.

## THE FIRST OBSERVED CASES OF FRIEDREICH'S ATAXIA IN AMERICA.

By J. H. KELLOGG, M.D., LL.D.
BATTLE CREEK, MICH.

THIS peculiar affection was first described by Friedreich of Heidelberg, Germany, after whom the disease was named, in a paper in Virchow's Archives in 1863. (Vol. XXVI, pp. 391 and 433). Other publications were made by Friedreich in 1864, 1876 and 1878. Friedreich regarded the disease as a hereditary form of locomotor ataxia. In 1883 an important paper in which a different view of the nature of the disease was presented was published in Germany by Rutimeyer (Virchow's Archive's, 1883, XCL, 106), and ten years later Pierre Nearie published in France a study of a large group of cases to which he gave the name hereditary cerebellar ataxia.

The following article was published by the writer in the *Archives of Electrology and Neurology*, edited by Dr. George M. Beard, New York, 1875, and republished in *Modern Medicine* for December, 1898:

"*Locomotor Ataxia in Children*—The patients, two brothers, were first seen by me about the first of May, 1875, and were under treatment and daily observation during the months of May, June, July, and August. They were aged, respectively, seven and ten years, and were of average development for their age. The younger of the two, when not in motion, gave every appearance of perfect health, and was a very mirthful, intelligent child. The symptoms of the disease were most marked in the older boy. The ataxia of his lower limbs was so great that he was unable to walk, yet there was very little loss of muscular strength, or of electro-muscular contractility, with slight decrease of sensibility in the lower limbs. He could only move about by creeping on his hands and knees. The ataxia symptoms were quite apparent, though less strongly marked, in the head and upper extremities. Speech was slow, indistinct, and difficult. Sight and hearing were both appreciably impaired, and there seemed to be difficulty in controlling the eyes. The face wore an expression of stupid imbecility; yet when aroused, the intellect did not appear to be greatly impaired. In the younger boy, the ataxic symptoms were almost wholly confined to the lower extremities. He could walk without much difficulty, though clearly manifesting the peculiar gait characteristic of the disease. His speech was distinct, and both sight and hearing were acute.

"The mother of the boys stated that the disease was first observed in the older one about four years previously, when he was a very sprightly, well-developed child, having been healthy from infancy. He could then speak distinctly, and could see and hear as well as others. The disease had progressed steadily from that time. Only about one year and a half had elapsed since the first symptoms were marked in the younger child; but the advance of the disease had been much more rapid than in his brother.

"In endeavoring to discover, if possible, the exciting cause of this grave malady, at so unusual an age, I was unable to fix upon anything which could be considered at all sufficient to account for it. Both parents were healthy and of good character and habits. I elicited, however, what seemed to me to be fair presumptive evidence that the predisposition to the disease at least was hereditary. The facts upon which this opinion was based, are these: (1) The same disease appeared in another child of the same family, a boy, and at about the same age. In this latter case it continued until it resulted in death from inanition, the muscles of deglutition being paralyzed at the age of twenty years. (2) The same disease also affected several children in the families of two sisters of the mother of the boys, pursuing the same course as in the last case referred to. In each of the three families there were other children who enjoyed perfect health.

"In all these cases various modes of treatment had been tried without the least apparent benefit. Magneto-electricity had been used, but without effect. I decided, in order to test the value of electricity as a remedy in this disease, to use no drugs,

*The "Gastric Introducer" can be obtained at Tiemann & Co., 107 East 28th St., New York City, N. Y.

especially as the latter had been faithfully tried without effect, but to confine the treatment wholly to electricity and simple measures for improvement of the general health. The plan of treatment followed during the whole time the patients were under treatment, was this:

"'Central galvanization, with prolonged application to the spine, every other day, with a current of ten or twelve Stöhrer cells; general faradization once a week; frequent sun baths, sponge baths, and daily friction of the whole skin with the dry hand, together with systematic active and passive movements of the lower extremities. The only additional measures were abundance of exercise in the open air, and a generous diet.'

"*Results of Treatment.*—For several weeks there was no apparent change, except that the progress of the disease was checked. This was especially noticeable in the younger boy. During the next few weeks there was a manifest improvement in both cases, which was remarked by all who saw them (they were much noticed). The improvement was decided in the younger boy, but the older one improved so much that he could walk with canes. During the last month there was no further improvement, and treatment was discontinued, as the parents were unable longer to bear the necessary expense, being some distance from home. From my observation of the effects of electricity in these cases, I am encouraged to believe that if it could be employed at an early period in this disease, it would not only check its further progress, but would effect a cure."

Directly after the appearance of the republication in *Modern Medicine* the writer received a letter from Dr. Charles L. Dana, of New York City, in which the cases above described were recognized as the first observations of Friedreich's disease made in this country. It is scarcely necessary to add that the hope expressed as to the curability of the disease by the use of electricity was not realized. The two cases described died two or three years later. A considerable number of cases treated since have seemed to be very materially benefited by systematic training of the muscles by exercises similar to those recommended by Fraenkel in the treatment of locomotor ataxia. In one case, that of a girl of twelve years, such marked improvement was made that the patient became able to swim and was greatly improved in walking and other movements.

## QUANTITATIVE COLORIMETRIC ANALYSIS IN AID OF CLINICAL DIAGNOSIS.

By RICH. WEISS, Ph.D., M.A., F.C.S.,
UNIVERSITY OF BASEL.
FREIBURG I. BR., GERMANY.

Clinical laboratory investigation is pursued as a matter of routine by almost all the medical institutions in the world, but only a limited number of private practitioners attempt to have all measures for the precise diagnosis in their own hands, and do not fear the tedious nature of many of the processes and the amount of time necessary for the performing of chemical tests required for the thorough diagnosis.

Recently considerable importance has been attributed to the quantitative analysis of cholesterin and uric acid in the blood, and particularly those medical men who are interested in the study of infantile disease have tried to work out fairly accurate methods for the quantitative estimation of the aforementioned substances. It is only quite recently that in the University laboratory of Freiburg Professor Autenrieth and his assistants have discovered methods which are easily carried out, and which are at the same time absolutely accurate. They are of great importance to the general medical practitioner, inasmuch as they can be carried out without recourse to expensive instruments or complicated chemical methods. I have modified them in order to bring them within reach of the general practitioner, and will describe them briefly here.

*Cholesterin in the Blood.*—Two c.c. of serum or 0.1 to 1 c.c. of fresh or dried tissue are placed in a 100-c.c. beaker and 20 c.c. of a 25 per cent. aqueous solution of caustic potash are added. The mixture is boiled in the water bath for 2 to 3 hours, cooled, and without being diluted, is placed in a separating funnel and thoroughly shaken for a few minutes with 2 or 3 times its volume of ether (about 40 c.c. ether are required for each shaking operation). After a deposit has formed and the ether solution is separated the remainder is again shaken up with the same quantity of ether. This is repeated about five times. The combined ether extracts are allowed to stand for a short time, the ether is filtered, and the filtrate distilled off. The residue, which consists of cholesterin, is dissolved in a definite amount of chloroform and used for the colorimetric determination.

Five c.c. of this chloroform solution are placed in a 10-c.c. graduated cylinder, and 2 c.c. of glacial acetic acid, and 0.1 c.c. concentrated sulphuric acid are added. The cylinder is now shaken and placed in warm water at 30° to 35° C, and kept in a dark place for 15 minutes. A small quantity of this solution which is green colored is then colorimetrically compared with a normal solution of cholesterin freshly prepared from pine cholesterin. The comparison is best performed in a colorimeter, for which purpose the instrument designed by Professors Autenrieth and Königsberger will give the quickest and most accurate results, and with which a normal cholesterin wedge is supplied.

The liquid to be examined is placed in the little trough which forms part of the instrument and is compared with the standard wedge also fixed into the instrument. The observation is made through a small window, behind which a Helmholz double plate is fixed. This plate is the essential part of the instrument, for by it the liquids, *i.e.* the standard and the specimen liquids are joined and seen together so closely that the slightest difference in the colors of the liquids can be observed. The position of the trough is fixed, but by a mechanical device the standard solution, which is provided in a suitable wedge, can be moved up and down, thereby with the least movement comparing different quantities of the standard solution with, of course, varying intensities of color before the eye of the observer. This shifting up and down is continued until the exact point is found at which the standard wedge shows identically the same color intensity as the specimen liquid in the trough which, it must be remembered, is seen simultaneously with the standard liquid. At the same time as the wedge a scale of figures is made to travel along a pointer, so that exactly at the point where both liquids show the same color a certain figure can be read off the scale. This figure is applied to a comparison scale, such as is provided with the instrument for any kind

of clinical examination—which will give direct readings of the quantity contained in the specimen, thus obviating all calculations.

*Uric Acid in the Blood.*—Two, five, or still better 10 c.c. of blood are mixed with a few milligrams of ammonium oxalate to prevent coagulation and the mixture is added to five times its volume of boiling 10 per cent. acetic acid, and reheated to the boiling point. The mixture is filtered and the coagulum mixed again with 200 c.c. of boiling water to which 1 gram of sodium acetate has been added. After five minutes it is again filtered. The collected liquids are evaporated until the volume approximates 3 c.c. and twice washed with 2 c.c. of a 0.1 per cent. solution of lithium carbonate into the glass tube of a centrifuge. Thereafter 5 drops of a 3 per cent. silver lactate solution, 2 drops of a magnesia mixture and 10 to 15 drops of ammonium hydroxide are added, and the mixture is centrifuged. The clear liquid is then poured off, the residue mixed with 5 drops of sulphureted hydrogen solution, and 1 drop of concentrated hydrochloric acid. The sulphureted hydrogen is driven off again by immersing the tube in boiling water until a 0.5 per cent. solution of lead subacetate does not produce a cloud. Water is now added and the mixture is again centrifuged. The clear liquid is poured into the separating cylinder, the residue twice washed again with hot water, the liquids being each time poured into the separating cylinder. Two c.c. of diluted sulphuric acid and 5 c.c chloroform are added and finally 1 c.c. of a 10 per cent. hydriodic acid, the mixture being gently shaken. The iodine liberated and dissolved in the chloroform is estimated as outlined above by means of the colorimeter.

## PATHOLOGY, ETIOLOGY, AND DIAGNOSIS OF TYPHOID FEVER.*

By G. A. RUECK, M.D.,

NEW YORK.

THE purpose of this paper is to review briefly the facts concerning the pathology, etiology, and diagnosis of typhoid fever which have been established by the researches of the pioneers of modern medicine, and which the busy practitioner has no time to read up in the original articles.

1. Pathology.—The cause of typhoid fever is the *Bacillus typhosus.* It was discovered in 1880 by Eberth, in the spleen and mesenteric glands of typhoid fever patients who had come to autopsy. The final proof of the etiological connection of this bacillus to typhoid fever was shown by Gaffky in 1884. The typhoid bacillus is a short rod, 1 to 3.5 microns in length, with a width varying from 0.5 to 0.8 microns. Its ends are rounded, but never club shaped. It forms no spores, is actively motile, and has twelve or more flagella, which are peripherally arranged. It stains with ordinary aniline dyes, and is Gram negative. In appearance it has nothing absolutely distinctive which could serve to differentiate it from bacilli of the typhoid-colon group. The typhoid bacilli are present in the circulating blood of all the patients during the entire course of the disease. According to Hiss they do not appear in the feces until the intestinal lesions are well advanced and ulceration is occurring (second week and later). In the urine the bacilli are present in about 25 per cent. of the cases during the early days of convalescence. In these cases albumin is present in the urine in considerable quantities. The bacilli usually appear and disappear with the albumin. In general the bacilli have not been found before the fifteenth day of the disease and examinations of the urine, therefore, can be of little early diagnostic value. He did not find the bacilli in 75 cases before the fourteenth day of the disease. They have been found for weeks, months and, in isolated cases, for years after convalescence, the examination thus having much hygienic importance. It is noteworthy also that in the course of and following typhoid fever there often occurs voiding of *B. coli* with the urine. The bacteriemia in these cases is due to two organisms, *B. typhosus* and *B. coli communis.* The typhoid bacilli are found in the gall-bladder at autopsy and at operations for cholecystitis months and years after the occurrence of typhoid fever. Miller of Johns Hopkins found it 7 years, von Dungern 15 years, Dowd of the General Memorial Hospital, New York City, 37 years after an attack of typhoid fever. In such cases the typhoid bacilli may be discharged from the intestine and prove a menace to the health of the community. An interesting example of such a typhoid carrier has been carefully studied and reported by Park. This typhoid carrier was within five years the cause of 26 cases of typhoid fever. Another remarkable case discovered by an investigator of the Department of Health of New York City on a dairy farm which shipped milk to a New York City dealer was found to have been an active typhoid carrier of forty-six years standing. A large milk-borne outbreak of typhoid fever in New York City was traced to this source. Neufeld found the typhoid bacilli in the rose spots in thirteen out of fourteen cases. In the sputum it occurs in rare cases complicated by bronchitis, bronchopneumonia, and pleurisy. It may be found in empyema usually accompanied by a mixed infection. The typhoid bacilli are probably also present in the cerebrospinal fluid of all the cases of typhoid fever, but there is at present not enough laboratory evidence to confirm this statement absolutely.

At autopsy the typhoid bacilli may be obtained from the blood, feces, urine, gall-bladder, rose spots, sputum, pus of empyema, and other suppurative lesions, from the ulcers in the intestines, the spleen, and often from the liver, kidneys, and cerebrospinal fluid.

*Lesions.*—In typical cases of typhoid fever the mucous membrane of the intestine is swollen and congested, presenting all the signs of an acute catarrhal inflammation. The characteristic lesions, however, are to be found in the Peyer's patches and solitary follicles. The lymphoid structures are invaded by the specific microorganism, become inflamed and proliferate actively. The Peyer's glands therefore are enlarged, soft, and intensely reddened, and project above the general surface as flattened plaques. The solitary follicles also may be so much swollen that they appear like little polypes on a slender pedicle. At the height of the first stage the surface of the affected plaques presents a curious grooved "beard-like" appearance. This appearance is due to the unequal swelling of the connective tissue stroma and the lymphoid elements. At the beginning of the second week portions of the affected follicles undergo a form of coagulation necrosis. The central parts slough away, leaving superficial erosions, which often as-

*Paper read before the Bronx Medical Association, September 3, 1913.

sume a brownish color from bile straining. In the course of the next few days the sloughing process gradually extends until well-defined ulcers are produced, having a fairly smooth base and swollen and infiltrated edges. The ulceration tends to penetrate into the depths, and usually extends as far as the muscularis mucosæ which may be recognized by its clear ribbed appearance. The well-defined, typical typhoid ulcer is somewhat oval, the long axis corresponding to the long axis of the bowel; the base is smooth, the edges comparatively thin and undermined. Small ulcers may be irregular, especially when they do not involve the whole extent of the Peyer's patch, or again, may be small and round, when involving a solitary follicle. As a rule, the most advanced ulcers are to be found in the region of the ileocecal valve and become less marked as one passes up the ileum. In very severe cases the last foot or so of the small bowel together with the head of the cecum may be converted into a large gangrenous eschar. The typhoid ulcer may heal without leaving any trace of inflammation at all, or, it may be replaced partially or entirely by scar tissue. Healed typhoid ulcers in which the lymphoid tissue has been entirely replaced by connective tissue may often be recognized as oval patches which are smooth, pigmented and somewhat depressed below the general surface of the bowel.

Coincidently with the intestinal involvement, the mesenteric glands and spleen are swollen, hyperplastic and inflamed. They may, as a consequence, be greatly softened. Spontaneous rupture of the spleen has occurred but is rare. Operations for this condition have been followed by death of the patients. There is only one case on record in which a patient was operated upon successfully for a ruptured typhoid spleen and recovered. The operation was done by William Downes upon his associate visiting surgeon, Dr. Hitzroth, in the New York Hospital, February, 1913. The mesenteric glands may undergo necrosis or suppurate. Perforation of the bowel is not uncommon and unless early recognized leads to a fatal peritonitis. Because of the peculiar asthenic type of the typhoidal infection and the fact that leucocytes are scanty and the exudate is poor in fibrin, adhesions do not readily form. Adami saw only two cases with adhesions in typhoid peritonitis. Perforation of the gut occurred according to Adami in 2.66 per cent. of 2,036 cases of typhoid fever treated at the Royal Victoria Hospital, Montreal.

Another dangerous complication is hemorrhage due to the erosion of some vessel in the ulcerated area. This accident occurred, quoting Adami again, in 6.04 per cent. of cases.

In the course of typhoid convalescence or during the later weeks of the disease suppurative lesions may occur in various parts of the body. The most frequent localization of these is in the periosteum, especially of the long bones and joints. They usually take the form of periosteal abscesses often located upon the fibia occurring either late in the disease or even months after convalescence and are characterized by very severe pain. Osteomyelitis may also occur but is comparatively rare. Typhoid spines are not uncommon. We had a case in St. Francis Hospital in 1909. The patient was put in a plaster-of-Paris jacket and recovered. Subcutaneous abscesses and deep abscesses in the muscles due to the typhoid bacillus have been described by Pratt. Synovitis may also occur. Meningitis due to the typhoid bacillus is not infrequent during convalescence. A case of primary meningitis has been reported by Farnet. Obstinate cystitis caused by typhoid bacilli may follow in the path of typhoid fever. Suppurative processes in the kidneys are less frequent. Peritoneal abscesses due to the typhoid bacillus have been reported. Zinsser has reported a case in which typhoid bacilli were found free in the peritoneal cavity during typhoid fever without perforation of the gut. In his thesis H. Woimant has collected from the literature a number of cases of peritonitis without intestinal perforation and reports in addition one such case personally observed. Isolated instances of typhoid bacilli in abscesses of the thyroid and parotid glands and in brain abscesses have been observed. Phlebitis due to typhoid fever is not infrequent. There are a few cases on record where the typhoid bacillus was found in the wall and endometrium of the uterus. Ricketts has collected from the literature 134 cases of typhoid gangrene of the lower extremities cured by surgical and spontaneous amputations. Typhoid fever without intestinal lesions may occur. An excellent summary of such cases, together with several personally observed has been given by Flexner.

*Definition:* From all the above mentioned findings of the different observers it is evident that typhoid fever is a general blood infection, a septicemia, due to the *B. typhosus*, with a most constant and characteristic localized process of acute inflammation in the intestines, and occasional suppurative lesions in various parts of the body.

*Etiology.*—Typhoid fever occurs in almost all parts of the world and is endemic in character. In the larger communities of the temperate zones epidemic exacerbations take place chiefly in the autumn. These epidemic increases are usually distinctly limited by the distribution of a particular water supply, and are the consequence of some defect in the system of sanitation. The disease is acquired by ingestion of the specific bacteria. Infection by any other channel than that of the alimentary canal has not, so far, been satisfactorily demonstrated. The bacilli leave the body chiefly in the feces and the urine, and there is great danger of contamination of all objects coming in contact with these substances. In the majority of cases typhoid fever is transmitted by the agency of the water. This was the case in the epidemic in Ithaca, N. Y., in 1903. In an analysis of 650 typhoid epidemics Schüder found 462 reported upon reasonable evidence as originating from water. In the statistical summary by Schüder, 110 of the 650 epidemics recorded, were attributed to milk. When contamination of milk has occurred it has often been traceable to the water used in washing the cans or to attendants employed at the dairies, who had been in contact with typhoid cases or who were convalescing from or actually suffering from the infection themselves. Excluding water and milk, all remaining causes of typhoid dissemination constitute about 12 per cent. and are found chiefly in the use of vegetables contaminated from infected soil and from the use of other food products. Conn found that oysters grown in waters close to sewage discharges may be the means of typhoid transmission. An epidemic occurring at Wellesley College was attributed by him to this cause. Foote demonstrated experimentally that typhoid bacilli may be found alive within oysters for 3 weeks or

more after they have disappeared from the surrounding water. Indirect contamination of food and water by flies and other insects has been emphasized by Veeder as one of the methods of typhoid transmission. He observed that in camps during the Spanish-American War flies in large numbers traveled to and fro between the sinks and cook-tents and he concluded that at least some of the typhoid fever occurring at that time may have been caused in this way.

*Diagnosis:* The chief symptoms of typhoid fever are the peculiar temperature curve (gradual rise, maintenance, slow descent); the pulse, which becomes early dicrotic; the comparatively slow respiration; the rose spots; the enlarged spleen, a distinct diazo-reaction in the urine, a positive Widal blood-serum test and cultures demonstrating the presence of the *B. typhosus* in the blood. Of some diagnostic value also are epistaxis, headache, and the absence of leucocytosis. Ordinarily a positive Widal reaction in dilutions of the patient's serum of 1:40 and more is considered to be specific, but a distinct agglutination appears in typhoid fever rarely before the beginning of the second week. It may then continue during convalescence for 6 to 8 weeks and in chronic infections of the gall-bladder due to *B. typhosus* for years. A blood-culture is therefore the most scientific way of making an early diagnosis in typhoid fever. The great majority of cases of typhoid fever are correctly diagnosed as such by competent observers within the first week or ten days; only in a small proportion the diagnosis remains uncertain for a longer period.

In conclusion, I believe that all cases of typhoid fever give the agglutination reaction at some time during the disease. Cases in which this diagnostic reaction is absent are caused by other organisms. I personally advocate for routine work the macroscopic instead of the microscopic agglutination test and in doubtful cases (1) the macroscopic agglutination test of the serum of the patient with different organisms, and (2) blood cultures of the organisms with the following necessary tests for identification.

1070 Tiffany Street.

## Medicolegal Notes.

**Agreement Not to Compete—Validity—Extent of Relief.**—A contract by which a physician employed as assistant for one year provided that it might terminate at any time when desired by either party, in which event the assistant would not open an office within the same town for the practice of his profession, was continued by a renewal from year to year by general agreement or acquiescence of the parties. It was held, in an action for an injunction to restrain the assistant from practicing medicine in the town, that all the provisions of the contract, so far as applicable, including the assistant's agreement not to open an office upon the termination of the employment, remained in force, and such provision applied upon a termination of the employment after the expiration of the period of one year. The continuation of the contract continued the restriction.

It was claimed by the defendant that the contract was invalid because it was (1) an agreement in restraint of trade; and (2) so inequitable, oppressive, and contrary to public policy as to be unenforceable in a court of equity. It was not claimed to be a contract in general, but only in partial, restraint of trade. It was held that a contract of this character, if not against public policy, is valid if it be founded upon a legal consideration and be reasonable. A contract in partial restraint of trade will not, as a rule, be held to be against public policy, unless it unduly interferes with the interests of the public. If its restrictive features be so large as to be likely to injure the public, it must be held contrary to the public welfare. A contract of sale restricting one entering a similar business in a limited area might not injuriously affect the public, while a contract restricting the exercise by one of his ordinary avocation might. In determining whether the public interest be involved in contracts restricting employment, we must keep before us the necessity of preserving inviolable the agreements of men so far as they be reasonable, and of maintaining the freedom of individuals to pursue their ordinary avocations. There is no attempt by this restrictive provision to restrain the defendant from pursuing in an extended territory his avocation for either an indefinite or a limited time.

The test of the reasonableness of the present contract was met by answering the question, Does it afford a fair protection to the interests of the employer in whose favor it is made? The area of restriction was limited to the place of practice. Without the aid of the restriction, the defendant having won the confidence of the plaintiff's patients, might breach his contract, and take away from him the very patients whose confidence he had gained while in the plaintiff's employ. There was no other effective way by which the plaintiff could protect himself in his livelihood except by preventing the defendant from wrecking his practice. The defendant insisted that there was a distinction between a business and a profession; that, while the period of restriction as to a business may be unlimited, the rule should not apply to a profession, since it is a purely personal relation whose benefits cease upon death or the cessation from practice.

The court did not think the distinction tenable. A profession partakes on its financial side of a commercial business, and its good-will is, it was held, often a valuable asset. While it is true that the profession has its personal side, the court considered that it is not true, except under exceptional circumstances, that a professional man is indispensable to any community. The distinction sought by the defendant is made in a few cases but generally the courts do not recognize it. The facts of the complaint—and each case must be governed by its own facts—showed no circumstances of hardship attendant upon the making of the contract and no advantage taken of the employee and no wider restriction than was reasonably necessary for the protection of the employer; therefore, it was held that the restrictive covenant could not be held to be unreasonable.

The restriction, though in specific terms not limited to time, was held to be, by the fair construction of other provisions of the contract, limited to the lifetime of the plaintiff. It was held to be proper for the court to anticipate the probability that the plaintiff might cease to practice, and to limit the period to the time during which he might be practicing.—Styles v. Lyon, Connecticut Supreme Court, 86 Atl. 564.

## CANCER AND PRECANCEROUS CONDITIONS.

THIS title was chosen by Rodman for the annual oration which was delivered before the Academy of Surgery of Philadelphia, October 6, 1913, and published in the January number of the *Annals of Surgery*. In it are contained a brilliant general review of some phases of the cancer problem besides some startling, but undoubtedly true, statements that should be given wide circulation among the general practitioners of this country. It is pointed out that in spite of the world-wide study of the subject in recent years, but little additional information has been given to the clinician to enable him to detect cancer in its early and curable stage, when it is believed to be a local affair and the diseased focus can be permanently eradicated. But, it is also suggested, "are we not * * * neglecting valuable means already at hand, facts proved to the hilt, which if employed rightfully and in time, would undoubtedly save thousands where hundreds are now being saved?" And then follow the startling statements, backed up by statistics, that 90 per cent. of the cases of cancer of the cervix and stomach are inoperable when first seen by the surgeon, and that the same thing is true of 29 per cent. of cancers of the breast, and of a larger number of the cases of cancer of the tongue and mouth. By this he does not mean that these cases "are unfavorable or fairly late ones but are actually inoperable, in other words, without a reasonable chance of removing the disease." What is the reason for such delay in getting these cases to the surgeon? In gastric cancer the physician usually "waits until he can by symptoms, signs, test meals, skiagrams, etc., make a *positive* diagnosis. When this can be done the case is no longer operable." Operations in such cases are at the best only palliative and often of doubtful benefit to the patient "while their deterrent effect upon others with operable conditions is far-reaching and permanent. To them their friend or acquaintance died, not from cancer, but from an operation; hence they themselves will have none of it." The situation is similar in cancer of the mouth, tongue, uterus, and breast.

Rodman lays considerable stress upon the harm that is done to the practice of surgery and, reflexly, to the early cancer patient by operating in cases where extensive metastasis has already occurred, and he believes that operations upon advanced cases "should neither be practised nor sanctioned, unless for the best of reasons." There is far from being unanimity of opinion, however, as to the limit of operability. Rodman says: "By inoperable we mean a condition no longer local but general and one which cannot, therefore, with reasonable certainty be extirpated on account of metastases to adjacent or distant tissues or organs." Strictly speaking, this would seem to rule out operation on the breast when the axillary glands are palpably enlarged; and yet, in these cases the enlarged axillary glands often, microscopically, show no sign of cancerous involvement. Deaver (*Jour. A. M. A.*, March 15, 1913) in 200 operations for cancer of the breast found the axillary glands palpable in 74 cases and of these 13 were found to be non-cancerous. There was certainly no way of determining before operation whether these glands harbored metastatic cancer cells or not, and the outcome proved that the patients were entitled to their chance. Again, we may sometimes suspect but cannot be sure that metastasis has taken place to distant and inaccessible regions. These patients are entitled to a chance, for our suspicions may turn out to have been based upon an incorrect interpretation of the symptoms. The limit of operability will long remain debatable, but Rodman certainly is right as to the harm that is done by operating in those cases in which there can be no question as to the extensive dissemination of the disease.

Rodman quotes as follows from the latest report of the Pennsylvania Cancer Commission: "In 3 per cent. of the cases of cancer of the breast the physician first consulted failed to make a local examination, and in 13 per cent. advised local applications or 'waiting to see what develops.' In gastric cancer the first physician consulted made no local examination in 9 per cent. and gave bad advice in 20 per cent. In cancer of the cervix no local examination was made in 10 per cent. and bad advice was given in 20 per cent. In cancer of the ovary no local examination was made in 14 per cent. and non-intervention was advised in all. * * * As a general average, cancer patients have been under the care of their family physician more than a year before they applied for a radical cure." Since, in many regions, the average time of appearance of lymphatic involvement is within one year, one can readily see what this delay on the part of the general practitioner is apt to mean to the patient; and this too without taking into account the much greater rapidity of involvement if it happens to be the medullary type of cancer, and the danger of metastases to the osseous system, especially to the vertebræ, or to other inaccessible regions. Operations for mammary cancer with axillary involvement yield 25 per cent. of cures, and 80 per cent. if operation is done before the disease has spread to the nearest lymph nodes, while a larger percentage of early, strictly local carcinomata of the lip and larynx yield to excision. Taking the cases as they come at the present time "carcinomata of the alimentary tract from mouth to anus are permanently

curable in about one-fourth of the cases; whereas carcinomata of the mammary gland give upward of 50 per cent. of 5-year cures."

Regarding precancerous conditions, Rodman remarks that we "should aim at something which will save nearly all instead of half our patients. There is but one way in which it can possibly be done and that is by operating in the precancerous stage. * * * Such precancerous conditions are inflammatory, inasmuch as a mild, low-grade, chronic inflammation, due to long-standing irritation and resulting in either ulceration, hyperplasia, or cicatricial tissue, is present in all of them. This, in turn, means diminished arterial supply with lessened physiological resistance of the cells undergoing metaplasia. While there may be in addition something more necessary, extrinsic or intrinsic, to initiate the cancer process, this much is always present, a suitable soil, if you please, and would seem enough in itself to cause cancer." The true cause of cancer is as yet undiscovered, but Rodman's suggestion as to the danger of leaving a suitable soil is well worthy of serious thought on the part of surgeon and practitioner alike. It is a matter of common knowledge in the profession that the sites of predilection of cancer are those situations that are most liable to traumatism of one kind or another; the cervix of the uterus, the breasts, the constricted portions of the alimentary tract, the tongue, the smoker's lip, the gall-bladder that is allowed to remain irritated by gallstones. Early removal or repair of the lacerated cervix is prophylactic surgery, surgery in what may well be a precancerous stage; and the same may be said of the removal of fibroadenomata of the virgin breast; the removal or drainage of a calculous gall-bladder. These are some of the points that every member of the profession should constantly bear in mind.

## DENTAL SEPSIS AND ITS RELATION TO THE GENERAL HEALTH.

It is only within recent years that the importance of oral and dental asepsis has been fully recognized. Possibly, in days gone by, a matter of fifty or one hundred years and more ago, teeth were sounder than they are now. The manner in which we live and the food we eat at the present time account to some extent for the frequently unhealthy state of the mouth, gums, and teeth. In any event, a thorough appreciation of the fact that a person with carious teeth carries within himself foci of infection which may terminate in serious disease, is of only comparatively recent date. Dr. William Hunter of London has been among the most insistent concerning the menace of oral sepsis. He has preached the gospel of the clean mouth with the greatest persistency for many years, and his crusade has had very beneficial results. The late Dr. Kinnicutt of New York was also very active in the same direction, and it may be now said that the public has become alive to the danger of the dirty mouth as a source of infection.

In the *American Journal of the Medical Sciences*, February, 1914, is a paper by C. N. B. Camac which he read at the meeting of the Association of American Physicians held in Washington, D. C., May, 1913. Camac in this paper discusses dental sepsis and its relation to the system. The necessity for careful radiographic examination of teeth and gums by an expert is emphasized as is also the need for loyal cooperation between the internist and dentist. Without such cooperation Camac points out the opportunity for treating a person afflicted with arthritis, brought about by infection from the teeth, is lost. Stress is laid upon the likelihood that vaccines are the only certain means of combating these destructive pyogenic infections in their advanced stages, and it is argued that the loss of the opportunity to procure this important therapeutic agent would be a serious and culpable omission. Setting aside the question as to whether the dental involvement is the cause or effect of a general sepsis, the clinical fact remains that the material procurable from such foci frequently offers the only chance of identifying the invading organisms and of procuring material from which vaccines may be made. The histories are given of several cases which were studied by Camac in cooperation with Drs. M. I. Schamberg, Alexander Currie, W. D. Tracy, and Harold S. Vaughan, dentists of New York City. The histories of these cases supply further direct evidence of the intimate relationship between dental sepsis and certain systemic conditions and strongly support the contention of the writer that a realization that one is dealing with abscess cavities, due possibly to the most virulent organisms, with the inevitable absorption of destructive toxins, is essential to the prompt and radical cure of such cases. Camac recommends that cultures should always be taken at the time of the removal of the tooth or the operation for draining the pus, and in the event of a positive culture, vaccines should be prepared and stocked in case they may be needed at some later date.

It really matters little whether intestinal stasis, as many say, is the primary cause of dental sepsis or whether the root of the trouble is in the teeth and gums and the alimentary tract is infected secondarily. Of course there is no doubt that when the vicious circle is established one condition reacts on the other, and the intestinal and digestive disorders *pari passu* with the dental sepsis become worse until a systemic toxemia is established with its long train of physical and mental ills. It goes without saying that both the digestive disorders and the oral sepsis should be treated as effectively as possible as it also stands to reason that so long as infection is present in the oral cavity little progress will be made in the treatment of the other complaints. It is an excellent augury for the future that dentists are taking a scientific and not merely mechanical interest in the condition of the teeth, and the plea of Dr. Camac that internists should cooperate with dentists in the effort to stamp out dental sepsis should be taken to heart by the medical profession.

## PUBLIC HEALTH WORK IN PORTO RICO.

A conspicuous feature of American rule in, or perhaps it would be more fitting to say protectorate over, tropical countries, has been the manner in

which hygienic conditions have been improved. Panama has become the classical example of how modern methods of sanitation intelligently and conscientiously carried out will convert a sink of disease into almost a health resort. The results in the same direction in the Philippines, although they have not been so much in the public eye, have been as noteworthy as those in Panama. Of the public health work done in Porto Rico little has been heard, in spite of the fact that a large number of carefully thought-out plans for coping with various tropical diseases and especially with uncinariasis have been brought or are being brought to a successful issue.

Dr. W. W. King, Surgeon U. S. Public Health Service, describes in "Public Health Reports" December 12, 1913, the work in which he has been engaged as a member of the Institute of Tropical Medicine and Hygiene of Porto Rico. The Institute was organized under the provisions of an act of the Legislative Assembly of Porto Rico, dated March 13, 1913. It was planned and organized by Maj. Bailey K. Ashford, Medical Corps, U. S. A.; Dr. W. F. Lippitt, director of sanitation of Porto Rico; Dr. Pedro Gutierrez Igaravidez of San Juan, and Dr. Isaac Gonzalez Martinez, director of the biological laboratory, service of Sanitation of Porto Rico. At the solicitation of the members of the institute, the governor of Porto Rico requested the Surgeon General of the Public Health Service to detail Dr. King as chief quarantine officer of Porto Rico and later as a member of the Institute.

The plan of the Institute work has three distinct periods: (1) Three months of instruction of sanitary official inspectors, etc. (2) Three months of expeditionary work in the interior mountainous districts. (3) Six months of research work at the laboratory and hospital at San Juan, including the study and examination of data and specimens collected during the expedition. The expedition had three aims: (1) Study of the diseases prevailing in the interior. (2) Establishment of a rural ambulant medical service. (3) Education of both planter and peon in elementary hygiene and sanitation.

The second object is one of immense importance to Porto Rico. The rural population of the Island, according to the census of 1910, was 79.9 per cent. of the whole. Of this number it is estimated by various observers that from 50 to 70 per cent. are in need of medical attention. Owing to various circumstances efficient medical attendance cannot be obtained in the country districts and the consequence is that the greater part of the rural population rely upon home remedies or upon the ministrations of some person in the neighborhood who has acquired a reputation for treating the sick. Dr. King explains the work of the expedition in detail and ends by stating that in the work of the technical commission special attention is at present being paid to the following diseases: *Schistosomiasis*, of which disease careful clinical and epidemiological notes are taken with a view of determining means of infection, intermediate host, and cure. King says that at the present time it seems rather difficult to reconcile Loos' theory of infection through the skin with conditions in Porto Rico. "*La Bonita*," a name given by some of the country people to an affection whose chief symptom is anasarca. It seems to be limited to the country districts and sometimes occurs epidemically. *Nephritis* is present in a large proportion of cases, and it is considered by some physicians to be an acute nephritis due to ordinary causes. It remains to be seen whether it is a disease entity or not. There have been a number of cases of *sprue* recorded from a part of the country where it was not believed to exist. In *Amebic dysentery* emetine hydrochloride has given excellent results. *Malaria*: so far only two barrios, or wards, of San Juan have been found infected. One focus is of the estivoautumnal type. *Venereal disease* is rarely found in the country districts. The cases of *uncinariasis* have not yet been counted, but it is estimated that this disease is still widely prevalent. The type of the disease is milder than that encountered formerly. Severe cases with less than 10 per cent. hemoglobin are, however, the commonest cause of grave illness. The presence of *trachoma* in Porto Rico is well known, but there are widely divergent opinions as to its prevalence and distribution. The work of the expedition was finished on December 15 and a further report will be issued later.

## SOME PHASES OF DISPENSARY WORK.

THE advantages of cooperation are perceived in the Association of the Out-Patient Clinics of the City of New York. The first annual report of this organization has just appeared. A wealth of data pertaining to the common interests of the dispensaries has been gathered, and a strong impetus has been given in the direction of improving the efficiency of dispensary service. Among the aims of the Association are the coordination of the activities of its members, the elimination of unworthy applicants for treatment, the creation of proper standards for treatment, and the promotion of economy in dispensary management.

The above report, detailing the progress that has been made during the first year of existence of the associated clinics, has appeared just at the time when a bill has been introduced into the Assembly of New York State, having for its object the abolition of all dispensary fees from patients. In other words, the aim of this bill is to make all dispensaries absolutely free to the poor. The apparent object of this measure, by wiping out the source of income from dispensary patients, is to reduce all dispensaries to a purely charitable basis, to make them more scrupulous as to the eligibility of their applicants for treatment, and to remove an important obstacle to the economic welfare of the medical profession. The claim may be made by those who advocate the abolition of the dispensary fees, that the various out-patient clinics vie with one another in increasing this source of their income, and that they are anxious to treat as many patients as they can, and in this way do not exercise sufficient care in weeding out unworthy applicants. This claim is, however, to be met by the answer that the associated clinics have already taken steps to limit the number of patients according to the facilities and size of the medical staffs

of the various institutions, and have furthered the long-established campaign of investigation as to the eligibility of all candidates for dispensary relief. It is believed by many that the abolition of the small fee which is charged to patients would be a mistake, and it is to be hoped, therefore, that the bill will not come to a vote without a full and free discussion.

One of the greatest evils in dispensary work at the present day is the careless and slipshod manner in which the treatment of patients is frequently carried on. There is an almost utter lack of standardization of efficiency. The pioneer labors in this direction of Michael Davis of the Boston City Dispensary should receive the hearty commendation of all who are interested in this subject. "Whatever is worth doing is worth doing well" finds its fit application in dispensary work.

Another serious evil of our dispensary system is the irregularity and tardy attendance of the physicians. This can be avoided by increasing the numbers of the members of the medical staff, or by duplicating the separate services in the dispensary. That is, instead of having only one children's service on any day, there should be two children's services which may be operated either simultaneously or in succession. This would, of course, prolong the hours of the clinics but it would make for more efficient work. There should be no reason why all the work of the dispensary is concentrated in the two or three morning or afternoon hours. The series of morning clinics and the series of afternoon clinics would prevent undue waiting, would serve the needs and convenience of a greater number of people, would extend the usefulness of the dispensary, and would utilize to the fullest extent the dispensary plant and equipment. It would require a greater expenditure for clerical and janitor help, but this expenditure would be small compared to the advantages that would be derived.

There should be a system whereby all dispensaries may obtain efficient laboratory aid in carrying on their work. There should be a clinical laboratory attached to at least one dispensary centrally located in every borough. The advantages of this are obvious. In cases in which such laboratory work has been attempted the lack of time and the stress of other work have prevented the physicians in attendance from devoting as much attention to it as they would like. Some dispensaries are attached to hospitals, and in these the hospital laboratory in some instances has undertaken the work of examining specimens sent to it from the different services in the dispensary. The result has been rather inefficient, for the hospital laboratory has done the work for the dispensary in a more or less stepmotherly fashion, and the dispensary physicians have hesitated to overburden the already overworked laboratory of the hospital.

Another matter that requires the close attention of all those who supervise dispensary work is the proper segregation and isolation of patients in the clinic waiting room. In many dispensaries it is not uncommon to see men and women in the same line awaiting their turn for medicine—mothers with babes in arms, genitourinary patients, young girls, children—no regard being paid by the dispensary attendants to the dictates of ordinary propriety. But this is not the most serious evil of the waiting room. It is only too frequent that the physician finds a case of diphtheria, measles, or scarlet fever among patients waiting for him, in some instances from two to four hours. If someone connected with the dispensary made a cursory examination of the people waiting their turn, he would pick out all suspicious cases and these could be kept in suitable isolation rooms, during the arrival of the physician. Such examinations should be made by one of the physicians who happens to arrive earliest at the dispensary, or by the different physicians in the dispensary in rotation. Happily, this mode of isolation has already been practised in a number of dispensaries, but it should be made compulsory in all institutions.

### Proposed Tax on Wood Alcohol.

THE fatalities resulting from the use of wood alcohol are numerous, and it is time that effective steps were taken to prevent its indiscriminate employment. The Secretary of the American Industrial Alcohol Association writing to the *New York Times* suggests that a simple and effective check to its indiscriminate use would be to place it under the rigid supervision of the Internal Revenue Bureau of the Federal Government and make it subject to an internal revenue tax varying from 2 cents to 10 cents per gallon, according to the degree of refinement. There is no necessity to guard against the use of crude wood alcohol, as its disagreeable smell is sufficient to prevent even those of very strong stomachs from taking it internally. A very different case is that of completely refined and deodorized wood alcohol, as this can be distinguished from pure grain alcohol only by expert tests, and in the opinion of the writer to the *Times* should be subjected to the maximum tax and a supervision as rigid as that governing the sale of taxed grain alcohol. It is suggested, moreover, that the law should provide that wood alcohol must be labeled poison, be sold in distinctive packages plainly marked, and its illegal use made subject to heavy penalties.

## News of the Week.

**Marriage Restrictions.**—A bill recently introduced into the New York State Legislature provides that before a marriage license shall be issued in the State both parties to the prospective marriage must file physicians' certificates to show that they are not afflicted with any physical or mental disease which is contagious or likely to become hereditary.

**Beth Israel Hospital.**—At the annual meeting of the Beth Israel Hospital Association in New York on February 26, the plans for the construction of the new building were discussed. The structure will be fourteen stories high, and will contain 500 beds. It is estimated that it will cost approximately $1,000,000. The report of the hospital showed that during the previous year 46,959 cases were treated.

**Hospital for Contagious Diseases.**—As a site for a hospital for contagious diseases, the City of New York has acquired an option on thirty-two

acres of land in the Edenwald section of the Bronx, just south of the Mount Vernon city line. This site has been selected because of the present undeveloped condition of the neighborhood, and because the large area will make possible the erection of many low buildings instead of a few high ones. The cost of land further south and the objections of residents in the populated neighborhoods have made it necessary to select for the hospital a site at the northern end of the city.

**Antivivisection Again.**—For the seventh consecutive year the attempt to secure legislation restricting vivisection in New York City was made before the Senate and Assembly Judiciary Committee in Albany on February 24, when representatives of numerous societies opposed to vivisection appeared to ask for the passage of two bills, one establishing a regulative commission and the other authorizing the appointment of an investigating committee. In opposition to the bills, Dr. Simon Flexner, Prof. Frederic S. Lee, and Dr. William P. Northrup appeared before the committee.

**Samuel D. Gross Prize.**—The Philadelphia Academy of Surgery announces that the Samuel D. Gross Prize of $1,500 will be awarded next year, and that essays in competition for it will be received until January 1, 1915. The conditions made by the giver of the prize are that it "shall be awarded every five years to the writer of the best original essay not exceeding 150 printed pages, octavo, in length, illustrative of some subject in surgical pathology or surgical practice, founded upon original investigations, the candidates for the prize to be American citizens." The essays, which must be by a single author and in English, should be sent to the "Trustees of the Samuel D. Gross Prize of the Philadelphia Academy of Surgery, care of the College of Physicians, 19 South 22d Street, Philadelphia," on or before January 1, 1915. Each essay must be typewritten, distinguished by a motto, and accompanied by a sealed envelope bearing the same motto, and containing the name and address of the writer. The committee reserves the right to make no award if the essays submitted are not considered worthy of the prize.

**Health of the Canal Zone.**—The report of the Department of Sanitation of the Isthmian Canal Commission for the month of December, 1913, gives the total number of deaths from all causes among employees during the month as 29, making an annual average death rate per 1,000 for the month of 6.91. The annual average death rate per 1,000 in the cities of Panama and Colon and the Canal Zone, including both employees and civil population, for the month was 26.92, which is nearly 6 points higher than for the same month of 1912. In segregating according to race, the annual average death rate per 1,000 from disease for employees was: For white, 1.33, and for blacks, 6.10, giving a general average for disease of 5.24. For the same month of 1911 the rate among whites was 5.71, and among blacks, 5.68, giving a general average of 5.68; and in 1912 among whites, 3.74, and among blacks, 5.56, giving a general average of 5.13. No cases of yellow fever, smallpox, or plague originated on or were brought to the Isthmus during the month.

**Civil Service Examination.**—The Connecticut State Civil Service Commission will hold an examination this month for the position of assistant in the State Hospital Service, there being at present a vacancy at the Connecticut Colony for Epileptics, at a salary of $900 per annum and maintenance. Candidates must be single, male, and graduates of a Grade A medical school, and have had at least six months' hospital experience. Application for further details should be made to the Civil Service Commission, Room 55, Capitol, Hartford, Conn.

**Col. William G. Gorgas**, who left South Africa for England on February 28 en route to the United States, will be entertained while in London by the British medical profession, as a mark of appreciation of the excellent work done in Johannesburg by him and his assistants.

**Food Inspectors Dine.**—The first annual dinner of the Food Inspectors' Association of New York was held in this city on February 28. Addresses were made by Health Commissioner Goldwater, Dr. M. B. McMillan, and Dr. Herman Betz.

**Jersey City Hospital.**—Plans are being made for the erection of a $250,000 addition to the Jersey City Hospital. The addition will be larger than the present hospital building.

**New York Milk Committee.**—The annual report of the New York Milk Committee states that the lives of 41,000 babies have been saved in this city during the last seven years through the cooperation of public and private welfare agencies. The report says: "During that time 950,000 babies have been born in New York City. If the infant death rate of the five years previous to the beginning of this work had prevailed there would have been 150,000 infant deaths instead of the 109,000 which actually occurred. On the other hand, if New York's low death rate of 1913—101.9 per 1,000 births—had prevailed throughout the seven-year period only 96,000 babies would have died of the 950,000 born." That this record is not due to favorable weather conditions or other accidental causes is shown by the increase in the number of infant deaths in Chicago, Philadelphia, and other large cities. A bill providing for uniform State regulation of the milk supply, which was defeated in the Legislature last year, will be reintroduced this winter with, the committee believes, strong prospects of success.

**Hospital Trustees.**—Gov. Glynn of New York has recently nominated the following persons for managers and trustees of various State institutions: The Rev. William H. Garth, Islip, Central Islip State Hospital; William D. Wolff and Edward J. Ward, Rochester, Rochester State Hospital; James M. Wells, Ogdensburg, St. Lawrence State Hospital; John C. R. Taylor, Middletown, Middletown Homeopathic State Hospital; Lizzie Wilhelm Constable, Utica, Utica State Hospital; Andrew J. Shipman, New York, Mohansic State Hospital; Daniel B. Murphy, Rochester, Craig Colony for Epileptics; the Rev. Chrisenberry A. Ritchie, Binghamton, State Hospital for the Treatment of Incipient Pulmonary Tuberculosis; Peter Sheridan, Rochester, State Soldiers' and Sailors' Home.

**City Death Rate.**—During the week ending February 21, there occurred in New York City 1,768 deaths, making a rate per 1,000 of 16.52, which is a decrease as compared with the same week of last year, when the total number of deaths was 1,836, and the death rate 17.83 per 1,000. There was a decreased mortality from diphtheria, influenza, pulmonary tuberculosis, and pneumonia, and an increased mortality from measles, scarlet

fever, digestive diseases, organic diseases of the heart, and nervous diseases. There was an increased mortality, also, in the age period below one year, a decrease between 1 and 5, and between 5 and 65, and an increase over 65.

**Charitable Bequests.**—By the will of the late Samuel K. Felton of Philadelphia, the sum of $10,000 is bequeathed to the Methodist Hospital of that city.

The Episcopal Hospital of Philadelphia receives $5,000 by the will of the late Countess Clara Roberts Galli, who died in Paris in 1911.

The will of the late Charles E. Dana of Philadelphia provides for the following contingent bequests: Wilkes-Barre Hospital, $10,000, and Children's Hospital of Philadelphia, $5,000 for the endowment of a free bed.

**New York Neurological Society.**—At the last regular meeting of the society the following officers were elected: *President*, Dr. Smith Ely Jelliffe; *First Vice-President*, Dr. E. G. Zabriskie; *Second Vice-President*, Dr. F. Kennedy; *Corresponding Secretary*, Dr. J. Ramsay Hunt; *Recording Secretary and Treasurer*, Dr. C. E. Atwood; *Councillors*, Dr. L. P. Clark, Dr. A. S. Taylor, Dr. F. Tilney, Dr. C. L. Dana, and Dr. I. Abrahamson.

**Tri-State Medical Association.**—At the annual meeting held at Wilmington, N. C., on February 19, the following officers were elected: *President*, Dr. E. C. Register, Charlotte, N. C.; *Vice-Presidents*, Dr. I. Allison Hodges, Richmond, Va.; Dr. Charles T. Harper, Wilmington, N. C., and Dr. F. H. McLeod, Florence, S. C.; *Secretary-Treasurer*, Dr. Rolfe E. Hughes, Laurens, S. C.

**Obituary Notes.**—Dr. Ralph Lyman Parsons of Ossining, N. Y., died February 26. He was born July 30, 1828, at Prattsburgh, Steuben County, N. Y., and was educated at Amherst College, from which he was graduated in 1853. He was graduated from the New York Medical College in 1857. He was the Medical Superintendent of the New York City Asylum for the Insane from 1865 until 1877. He was the Medical Superintendent of the Kings County Asylum for the Insane from 1877 to 1878. In 1880 he established a private hospital for mental and nervous diseases at Ossining, N. Y., of which he was the Physician-in-Charge at the time of his death. Dr. Parsons was the author of numerous papers dealing with the care and treatment of the insane. He was a Fellow of the New York Academy of Medicine, the New York Neurological Society, the New York State and County Medical Societies, the Society of Medical Jurisprudence, the American Medico-psychological Association, and the American Neurological Association. He is survived by a son, Dr. Ralph W. Parsons, and a daughter.

Dr. Ira D. Hopkins of Utica, N. Y., a graduate of the University of Buffalo, Medical Department, Buffalo, N. Y., in 1859, died at his home on February 23, aged 81 years.

Dr. Gilford E. Young of Forest City, N. C., a graduate of the Jefferson Medical College, Philadelphia, in 1870, died at his home, from paralysis, on January 30, aged 69 years.

Dr. Bliss S. Thorne of Havelock, New Brunswick, a graduate of the New York University Medical College in 1864, died at his home, on January 26, aged 78 years.

Dr. Stanley Howard MacGillvary of Brooklyn, N. Y., a graduate of the Bellevue Hospital Medical College, New York, in 1890, and a member of the New York State and Kings County Medical Societies, and the Associated Physicians of Long Island, died at St. Mary's Hospital on February 17 following an operation for appendicitis after a short illness, aged 45 years.

Dr. Marshall R. Glenn of Asheville, N. C., a graduate of the Jefferson Medical College, Philadelphia, in 1909, died at his home, after a long illness, on January 24, aged 31 years.

Dr. Lewis A. Snell of Charlotte, Mich., a graduate of the Chicago Homeopathic Medical College in 1886, died suddenly, at Los Angeles, Cal., on January 21, aged 72 years.

Dr. Lazarus Schoney of New York, a graduate of the University of Pennsylvania, Department of Medicine, Philadelphia, in 1867, chief contract surgeon in the United States Army during the Civil War, and formerly professor of pathology at the New York Eclectic Medical College, died at his home from heart disease on February 17, aged 76 years.

Dr. Albert H. Tompkins of Jamaica Plain, Mass., a graduate of the Boston University School of Medicine, Boston, in 1875, and a member of the Massachusetts Homeopathic Medical Society, died at his home after a short illness, on February 14, aged 70 years.

Dr. James S. Watson of Aurora, Ill., a graduate of the University of Michigan, Department of Medicine and Surgery, Ann Arbor, in 1881, died at his home suddenly on February 12, aged 62 years.

Dr. Gaius J. Jones of Cleveland, Ohio, a graduate of the Cleveland University of Medicine and Surgery in 1872, professor of medicine and physical diagnosis in the Cleveland-Pulte Medical College and formerly dean of the college, a member of the American Institute of Homeopathy, and attending physician to the Cleveland Homeopathic Hospital, died at his home on February 7 after a lingering illness, aged 71 years.

Dr. Robert C. Moon of Lansdowne, Pa., a graduate of the Jefferson Medical College, Philadelphia, in 1886, died at his home on February 13, aged 70 years. Dr. Moon had long been known for his work among the blind. He was a son of Dr. William Moon of London, England, who was himself blind and the inventor of an embossed type, and Dr. Robert Moon began early to assist his father in preparing geographical and astronomical maps for the blind as well as by transcribing with embossed type a considerable amount of literature in various languages. He continued the work in this country after completing his medical course, and served as secretary of the Home Teaching Society and Free Circulating Library for the Blind, as president of the Chapin Memorial Home for the Aged Blind, as treasurer of the Blind Relief Fund, and as a member of the Advisory Board of the New York and the Pennsylvania Associations for the Blind.

Dr. Matthew James McKinnon of York, Pa., a graduate of the University of Maryland, School of Medicine, Baltimore, in 1853, a surgeon in the United States Army during the Civil War, dean of the York Hospital Board, and a member of the Medical Society of the State of Pennsylvania, and the York County Medical Society, died at his home on February 23, aged 82 years.

Dr. John Pringle of Harrison, N. J., a graduate of the University of Glasgow, Scotland, in 1875, president of the East Newark Board of Health, and

a member of the Medical Society of New Jersey and the Hudson County Medical Society, died at his home from pneumonia on February 25, aged 67 years.

Dr. Frederick Farnsworth of New London, Conn., a graduate of the Bellevue Hospital Medical College, New York, in 1867, died at his home after a long illness, on February 23, aged 71 years.

Dr. W. Edson Apple of Philadelphia, Pa., a graduate of the Jefferson Medical College, Philadelphia, in 1898, and formerly a surgeon in the United States Army, in which capacity he had served in Porto Rico and in China, died at the Episcopal Hospital, Philadelphia, from blood-poisoning, on February 15, aged 36 years.

Dr. Frank A. Sharp of Philadelphia, Pa., a graduate of the Jefferson Medical College, Philadelphia, in 1872, and for thirty years physician to the Moyamensing County Prison, died at his home on February 16, aged 63 years.

Dr. Herbert F. Heilner of Scranton, Pa., a graduate of the Hahnemann Medical College and Hospital, Philadelphia, in 1887, died at his home on February 19, aged 50 years.

Dr. E. E. Klutz of Troutmans, N. C., a graduate of the Medical College of Virginia, Richmond, in 1884, and a member of the Medical Society of the State of North Carolina and the Iredell-Alexander Counties Medical Society, died at his home from peritonitis on February 16, aged 58 years.

Dr. Clemens Fulda of Brooklyn, N. Y., a graduate of the New York University Medical College in 1879, died at his home on February 26, aged 65 years.

Dr. Storm White, director of the pathological laboratory at the Metropolitan Hospital, Blackwell's Island, New York, and a graduate of the New York Homeopathic Medical School and Hospital in 1878, died at the Metropolitan Hospital, after a short illness on February 26, aged 56 years.

## Correspondence.

### OPEN-WINDOW SCHOOLS.

To the Editor of the Medical Record:

Sir:—In the issue of August 2, 1913, the Medical Record quoted an article from *American Journal of Public Health*, Vol. III, No. 2, relating to "Open-Window School Work in Philadelphia," and the editorial comment on the same concluded with the following remark: "It will be interesting to know the result of a second year's trial of the fresh-air school for healthy children."

The first class was organized at the Alexander Dallas Bache school in September, 1912. From the beginning it was very popular with both pupils and parents. In September, 1913, a second class was organized. One class is made up of first and second grade children and the other of third and fourth grade.

These classes have been composed of anemic, undersized or undeveloped children. Because of their weakened physical condition such are generally the first to contract colds and various children's diseases. That the cool fresh air treatment has partly prevented this will be shown by the percentage of attendance since the organization of open-window classes, in comparison with that of children of the same grades in the balance of the school.

| | Percentage of Attendance | |
|---|---|---|
| | School 3rd Grades (Warm Air) | 3rd Grade Open Window |
| Sept., 1912 to Jan., 1913 | 84 | 83.2 |
| | School 3rd & 4th Grades (Warm Air) | 3rd & 4th Grades Open Window |
| Feb., 1913, to June, 1913 | 89.2 | 88.5 |
| | 3rd & 4th Grades | 3rd & 4th Grades |
| Sept., 1910, to Jan., 1914 | 90.9 | 87.4 |
| | 1st & 2d Grades | 1st & 2d Grades |
| | 89.0 | 89.6 |

As a rule it is irregular attendance, not poor mind quality, that causes delicate children to fall behind in their studies. The following percentages of *promotions* show that the open-window children at the time of promotions compared favorably with pupils of parallel grades in warm-air classes in the same school.

| | Percentage of Promotion | |
|---|---|---|
| | 3rd Grades (Warm Air) | 3rd Grades Open Window |
| January, 1913 | 75 | 88.1 |
| | 3rd & 4th Grades | 3rd & 4th Grades |
| January, 1914 | 76.4 | 82.8 |

"I am convinced," says the school principal, "that cold fresh air is more stimulating to mind and body than air generally found in school rooms heated to 65° to 70° Fahr.

Walter W. Roach, MD.,
Supervisor of School Medical Inspectors,
5th & 6th Dist., Philadelphia.

### OUR LONDON LETTER.

(From Our Regular Correspondent.)

HISTORY OF MEDICINE—DEBATE ON VACCINE THERAPY—DR. ADDISON AND THE INSURANCE ACT—ST. GEORGE'S HOSPITAL DISPUTE ITEMS.

London, February 13, 1914.

When the Royal Society of Medicine resolved itself into a number of sections, there were not a few who thought there was no occasion for one on the history of medicine. So far, however, this may be said to have succeeded in providing interesting subjects to talk over. Take an example or two—Sir Ernest Clarke has adduced some new facts about Oliver Goldsmith. The origin of his medical degree has puzzled many. In his first book with the name on the title page, it stood as "Oliver Goldsmith, M.B." Whence the M.B., asked his biographers, and as they could not find out guessed it must be foreign. Now Goldsmith was B.A. of Dublin (1749) and would have been entitled to M.B. at the end of his medical education on completing some formalities. But part of his curriculum was taken in Edinburgh and part abroad, and the university records at that time seem all to have been carelessly kept. Goldsmith was known to have visited Oxford in February, 1769, but there, too, the university records seem defective.

Recently at the instigation of Sir Wm. Ogle a search in the local newspapers of the time has revealed the following entry in the *Oxford Journal* February 18, 1769: "Yesterday Oliver Goldsmith, Esq., Bachelor of Physics in the University of Dublin, author of 'The Traveler, a Poem,' of 'The Present State of Polite Learning in Europe,' and of several other learned and ingenious performances, was admitted in congregation to the same Degree in this University." That surely will be accepted as evidence that Goldsmith was given an Oxford *ad eundem* degree on the ground that he was a medical graduate already of the Dublin University.

"Roman Medicine and Roman Medical Inscriptions found in Britain" was the subject of a contribution to the Section by Dr. H. Barnes, who thought a new order of practitioners appeared under the Empire and mentioned a number of names that have

come down to us. Illustrations of inscriptions and sculptures he shows on the screen. Several appeared to have been dedications to Æsculapius; some of them having been found on the Roman wall and some in Greenwich park. Dr. Barnes also showed some Donaria, one a votive offering concerning a case of goiter, another a feeding cup for invalids. He gave, too, a description of Roman medicine stamps found in Britain and quoted Camden's statement as to the foresight of Roman soldiers who "did plant everywhere in old time for their use certain medicinal herbs for to cure wounds."

"Two Early Eighteenth Century Treatises on Tropical Medicine" were the subject of a contribution to the Section by Dr. Chalmers and Captain Archibald.

Nor can I omit to mention Dr. J. D. Rolleston's paper on the "Medical Aspects of Greek Anthology," showing by means of numerous allusions to medicine and diseases that the subject deserved more attention, and one must admit that it offers abundant scope for the scholarly medical man's study of everything in the life of the ancient Greeks which is concerned with medicine.

Another paper with a classical tone was "Martial and Medicine" by Dr. Crawford, who quoted references to medicine in the epigrams and gave us versified translations.

The discussion on "Vaccines from the Standpoint of the Physician" from which much was anticipated by some was elaborate enough, occupying two evenings at the Medical Section (R. S. M.), but does not seem to have contributed appreciably towards a definite result. The president, Dr. S. West, announced at the opening that the special points for consideration were: (1) the contraindications; (2) cases in which vaccines had been used and had failed, and were abandoned, and the reasons for this; (3) cases in which definite ill-effects had been produced by them. In the opening paper Dr. Horder said there were three types of vaccines: (1) autogenous, (2) stock vaccine, and (3) phylacogens—representing in this order their efficiency. But the merits of vaccine-therapy rested almost entirely on the final class. He admitted failures to be more common than successes, though he did not doubt the efficiency at times. The collection should not be entrusted to others. The limitations of the treatment were many. Cases of general infection seldom yielded. In typhoid it was some help, but did not shorten or modify the disease.

Dr. Briscoe said bacilluria when causing symptoms, was rapidly relieved. So was rheumatoid arthritis, where possible an infective focus should be removed or relapse would occur when the injections were discontinued. He reported good results in some cases after recognized treatment had completely failed. Dr. Gillett said some 75 per cent. of his chronic bronchitis cases had responded favorably to autogenous vaccine; some with great dyspnea; but some cases proved obstinate. Dr. Abraham reported little or no benefit and held it should not be resorted to in cases amenable to other treatment. In one case he thought death accelerated by it.

At the second meeting (on the 3d inst.) Dr. J. D. Rolleston remarked that those who had several successes in succession, fascinated by a new conception of a rational treatment, were apt to be optimistic, but their opinion might be modified by time. Pessimists, on the other hand, would attribute any good results to coincidence, suggestion, or association of other treatment. He took a middle position of open-minded doubt. The problem of immunity was complex and the technique might be at fault rather than the principle. The conditions of culture on artificial media might modify the products of the microorganisms. Vaccines had also been used in improper ways. Their results were so uncertain that their use was only justifiable when other methods failed or did not exist. Dr. Carmalt Jones was confident that the principle was sound, and if ever the control of infection became possible it would arise out of the methods they were employing now. All sources of irritation, pus, sequestra, dead tissue, foreign substances, must be removed. The correct organism must be used in suitable doses. He was satisfied some benefit had been obtained in pyorrhea alveolaris, bronchial asthma, and rheumatoid arthritis. In the mouth by streptococcal vaccines co-operating with the dentist. In asthma when excited by infected and inflamed bronchi. In rheumatoid arthritis there was no known definite bacteriology, so the treatment was quite empirical; but by trying organisms from the gums, urine, and feces good results were obtained. Dr. N. Raw had treated over 200 cases of lobar and broncho-pneumonia. To be of any use vaccines must be given at the outset—not later than third day—so stock vaccines had to be used—a considerable disadvantage. He had seen no bad effect. It was not a specific but a valuable aid. Dr. Harmer found some good results in affections of the upper air passages. Vaccines would cure colds, pharyngitis, and laryngitis; these are often due to *Micrococcus catarrhalis* and *Bacillus influenzæ* in combination. He reported some cases in which there had been a temporary ill effect. Dr. Agnes Savill said she discovered in 1908 the germ of acne and large doses of it were of unique value in seborrhœa oleosa and baldness. She had recorded twenty cases of benefit or cure. Dr. Nabarro was convinced of the value of the method in infections of the respiratory and urinary tracts. Dr. Bezly Thorne reported three cases of impaired health remaining after other treatment had nearly restored, but this indefinite condition was removed by autogenous vaccines. Lt.-Col. E. H. Elliot, I.M.S., said much optic neuritis, atrophy, and iritis in the East seemed due to pyorrhea and yielded to vaccines. Staphylococcal vaccines gave good results in the large boils seen in the East, and in the accompanying rheumatic pains and in asthma. He was told of better results still with anti-plague serum and he thought there was something in vaccines beyond the specific element.

The foregoing notes on this debate must not be considered a report. I have only selected a point or two from each speech, thinking you may like to know what is going on here as to this much-vaunted method. I cannot help remarking how much the case rests on its association with other treatment, so that if we admit the vaccines have value it is impossible to estimate to what extent. There is no evidence, such as we demand for other additions to our therapeutic measures. I sympathize with the president, who, in summing up, said the results in acute infections were eminently disappointing, though strikingly valuable in a few cases. But these few could not establish the good effects of the treatment. The manner in which vaccines had been used throughout the country was essentially unscientific and could do little good and harm had been done in some cases. Another point brought out was that other treatment must be used with it.

It was difficult to compute the value of a method without knowing the natural course of the untreated disease.

Dr. C. Addison, M.P., was entertained at a dinner last Friday by admirers of the Insurance Act. The Chancellor of the Exchequer took the chair and in a complimentary speech let out a little bit of the secret history of the Act to the effect that he was guided by the doctor as to the effect of his measure on the medical profession. Dr. Addison, he declared, is a politician as well as a doctor, and was not unmindful of the interests of his profession. He had depended on him to advise and instruct and had never been let down. "With all his mildness and gentleness of disposition," said the chancellor, "our friend is a first-rate fighter, a man to go hunting tigers with." Then he added: "I have been hunting tigers with him and we have both got out of the jungle." In his reply Dr. Addison expressed the honor they felt at Mr. Lloyd-George's presence and said some might not agree with his politics, but wherever they went they would find some who blessed his name and some who did the opposite.

Yesterday the Governors of St. George's Hospital met and considered the differences which led to the resignations of the treasurers followed by that of the president (Princess Christian). An effort to show that "an unfortunate misunderstanding" was all that occurred does not seem very convincing. It is pretty clear to outsiders that the managers muddled the matter and resolutions taken are only attempts to cover up the subject and prevent further public discussion. Whatever was the cause of charges made and the resignation of the treasurers, when the Princess, as president, proposed that an independent committee should investigate the matter, it was madness to suffer any opposition to so reasonable a step. When Her Royal Highness found some persons objected or questioned her right as president to request (or as one speaker said, "perhaps it was more than a request") such an inquiry resignation naturally followed. It seems a pity for a noble institution to have been exposed to such a misfortune. The governors have placed "on record the right of the president to institute such an inquiry."

A fund is being raised to form a permanent endowment of the late Sir Jonathan Hutchinson's museum at Haslemere. It was maintained by him up to his decease and has been kept up since by the family.

Mr. Mayo Robson has met with an unfortunate injury while touring in East Africa. He was accidentally shot in a buffalo hunt. He received flesh wounds in both thighs and had to be carried some 40 miles to Fort Hall. He has telegraphed to his brother that he is doing well.

Miss J. A. H. Cock, L.R.C.S. Ed., M.D. Brussels, Dean of the Royal Free Hospital Medical School for Women, has died in her fifty-fourth year.

---

**Rupture of Choroid in a Myope, Following Parturition.**—A. S. Cobbledick reports the case of a markedly myopic woman aged 31 years, who had been delivered by means of forceps five months previously. As soon as she got about—ten days after the birth of the child—she noticed a dark patch in front of the right eye. It is still dark and diamond-shaped, close to the center of vision. The right eye has been tender to touch. There is a choroido-retinal tear extending from the outer side of the posterior staphyloma outwards and slightly upwards—somewhat fusiform in shape with a patch of pigment on each side of the rupture at its widest part. There is no history of previous traumatism.—*Proceedings of the Royal Society of Medicine.*

## OUR VIENNA LETTER.

(From Our Regular Correspondent.)

NATURE AND TREATMENT OF PAVOR NOCTURNUS AND ITS EQUIVALENTS—TEST FOR GASTRIC ACIDITY WITHOUT THE STOMACH TUBE—POSTANGINAL NEPHRITIS—RENAL DIABETES—EXTIRPATION OF MENISCI OF KNEE JOINT—HERPES ZOSTER OF THE BLADDER.

VIENNA, February 1, 1914.

IDIOPATHIC pavor nocturnus occurs in children who awake from sleep with signs of marked fear. They are unconscious and only appear to be awake; in fact, they are in deep sleep. The cause of the manifestation is the following: the children are dreaming of an exciting occurrence of the day, which perhaps produces fear. The attacks are repeated in a typical manner for several days and even for many weeks, during which the content of the dreams is always the same. The stereotypy of the attacks is to be explained by the stereotypic and monotonous course of the last hours before going to bed. In the same class as pavor nocturnus one can place its equivalents, which consist of fits of coughing, vomiting, or pains, etc., during sleep. One characteristic is that the children cannot remember their dreams or fits. The therapy consists of suggestion while the children are awake "Wachsuggestion." One prescribes, for instance, 5 or 10 drops of tinctura amara or tincture of cinchona, with which remedy one may guarantee success with absolute certainty. Of course, the children must know exactly the aim of the treatment. With this treatment one can cure every case of pavor nocturnus, although one is not assured that relapses will not occur.

A method of testing for muriatic acid in the stomach contents without the use of the stomach tube is to be applied in cases in which the introduction of the stomach tube is not indicated or is not permitted by the patient. Späth has already described a method, according to which the patient has to swallow a silk thread colored with Congo red, on which hangs a lead globule. As the extraction of the globule causes disagreeable sensations to the patient, Dr. C. Schwarz has modified this method in replacing the lead globule by a gelatine capsule filled with pulverized metallic bismuth, barium sulphate, etc. After the extraction the thread becomes more or less blue, according to the acidity of the gastric juice. In cases of a total want of hydrochloric acid the thread remains red. During the discussion several opinions were given that this method is an unreliable one and that preference should be given to the stomach tube.

Nephritis after angina (postanginal nephritis) was discussed at a meeting of the Practitioners' Society of Vienna. Pribram presented four cases in which there occurred after follicular tonsillitis a nephritis with albumin and casts in the urine, with edema of the face and feet and increased blood pressure. In all cases the symptoms disappeared after the performance of tonsillotomy; but this operation is indicated only in cases of chronic inflammation. As a result of the suppurative focus in the tonsils the glomeruli of the kidneys are secondarily affected.

"Renal Diabetes" was the subject of a paper by Professor Hugo Salomon who explained that the prognosis in cases of this condition is a very good one. The influence of the food upon the secretion of sugar is rather small, the content of sugar in

the blood is comparatively low (0.08-0.15, and in healthy persons 0.07-0.01). Salomon has observed 40 cases of renal diabetes and only in some of the cases was the content of sugar in the blood increased. According to the latest researches the previous existence of a nephritis is not necessary. Renal diabetes shows a certain resemblance to ordinary diabetes in the fact that one can cause it to disappear by the withdrawal of carbohydrates.

Of great interest is a case of extirpation of both menisci of one knee joint after an injury. As a result of the operation performed by M. Hirsch the function of the joint was in no way disturbed.

The diagnosis of herpes zoster of the bladder *in vivo* is a rare occurrence. R. Volk made this diagnosis in a man in whom during the course of a herpes zoster of the skin a hemorrhagic cystitis appeared. The latter condition disappeared with the subsidence of the herpes. The urine was sterile on repeated examination. A similar condition of the bladder has been observed in scarlatina, erysipelas, and purpura.

## OUR LETTER FROM THE PHILIPPINES.

(From Our Regular Correspondent.)

OFFICERS OF THE MANILA MEDICAL SOCIETY—CHOLERA UNDER CONTROL—HEALTH CENSUS OF MANILA—SEARCH FOR DYSENTERY CARRIERS AMONG COOKS AND WAITERS—SECOND BIENNIAL CONGRESS OF PHYSICIANS AND PHARMACISTS OF THE PHILIPPINE ISLANDS.

MANILA, P. I., January 21, 1914.

THE regular monthly meeting of the Manila Medical Society was held January 5, 1914, at the College of Medicine and Surgery of the University of the Philippines. The following officers were elected for the current year: *President*, Dr. B. C. Crowell; *Vice-President*, Captain Ernest R. Gentry; *Secretary and Treasurer*, Dr. John A. Johnston. No papers were read at this meeting.

The cholera situation in the Philippines is apparently still under control. The disease is eradicated almost immediately in any town in which it makes its appearance, but new centers of infection are constantly coming to light. In many of these it is practically impossible to trace the first cases to any previous case. The hypothesis is gradually gaining ground that cholera organisms are constantly present in the intestines of some inhabitants of the Philippines, but that perhaps their morphology is so changed that it is not possible to recognize them by present laboratory methods. Then, for reasons not as yet understood, the organism reaches a stage in its cycle in which it again becomes effective, and if the feces of such an individual contaminate the food or drink of a more susceptible individual a case of cholera results. If such a case is promptly discovered and the stools properly disinfected, a more serious outbreak or an epidemic is avoided. If the cases are not promptly discovered and a number of passages through human intestines take place, the cholera organisms gain in virulence and if the conditions are favorable other individuals become infected and an epidemic soon results. The foregoing hypothesis is apparently also supported by experiences with residents of other countries. For instance, on January 3, 1914, there arrived in the port of Manila the steamship *Prinz Sigismund*. The ship's surgeon reported four cases of beriberi among Chinese passengers who had embarked at Rabaul, New Guinea, about ten days previously. Twelve hours after the vessel arrived in port one of the cases died. The autopsy showed lesions of both beriberi and cholera. Cultures made from the intestines were positive for cholera vibrios. On January 10, 1914, a Japanese steerage passenger arrived on the steamship *Chicago Maru* from Japan. In making the routine stool examination, which invariably is made in the case of all steerage passengers entering the Philippines, the woman was discovered to be a true cholera vibrio carrier.

Under the joint auspices of the Police Force and the Bureau of Health a health census of the city of Manila is being made. This will include the number of males and females of each nationality in age groups, under the plan followed by the United States Census. In addition, it will include a count of the number of houses in the city of each type—that is, whether constructed of strong material, of light material, or of mixed materials.

In view of the progress which has recently been made with regard to the etiological factors concerned in amebic dysentery, the Bureau of Health is now about to undertake a stool examination of all of the servants in hotels, boarding houses, hospitals, and other institutions with a view to ascertaining whether there are any cases of amebic dysentery or ameba-carriers, especially among the kitchen and dining-room service personnel.

The Second Biennial Congress of Physicians and Pharmacists of the Philippine Islands will take place in Manila from February 10 to February 14. This organization is composed almost entirely of Filipino physicians and it is estimated that at least 300 members will be present. The work of the Congress has been divided into a section on medicine; a section on obstetrics and pediatrics; a section on surgery, gynecology, ophthalmology, rhinology, pathology, neurology, and orthopedics; a section on public hygiene, legislation, sanitation, and legal medicine; a section on pharmacy, which is divided into a division of professional interest to pharmacists, a division of applied chemistry, a division of vegetable pharmacology, and a division of pharmaceutical legislation. The Congress is under the presidency of Dr. Fernando Calderon, with Dr. Manuel S. Guerrero, general secretary, and Dr. Joaquin Quintos, general treasurer.

Dr. Vicente de Jesús, who entered the service of the Insular Board of Health January 24, 1902, and lately has occupied the position of medical inspector, has been named assistant director of health by the Governor-General.

2. **Prognosis of Sarcoma of the Testicle.**—E. A. Codman and R. F. Sheldon present an analysis of the statistics of this condition as observed at the Massachusetts General Hospital. These statistics give the mortality from the disease as 61.9 per cent. Excluding those not operated upon in which the condition of the testicle was manifestly inoperable, or else discovered at autopsy in

deaths from entirely different diseases, the mortality is reduced to 58.93 per cent. This is a large figure, but it is much smaller than is usually taught. Thus out of fifty-six cases operated upon thirteen are living (average time after operation nine years; extremes, two and twenty-eight years), and ten have died from something else (average time after operation, ten years; extremes, seven months and twenty-six years). That is, twenty-three or 41.07 per cent. of those operated upon survived the disease. If eight unoperated cases and twelve cases operated on when metastases were evident are excluded, one finds that 52.27 per cent. were cured. It is concluded, therefore, that the prognosis of sarcoma of the testicle, while bad, is not, when the condition is operated upon, so universally bad as textbooks would lead one to infer. The significant points are as follows: Of the thirty-three operated cases which died from the disease, twenty-one had no sign of metastasis at operation, yet death occurred in all within three years. Only twelve showed metastasis at operation; in spite of the fact that in two of these additional dissection was done, all were fatal. The authors' figures confirm those of Chevassu, which show that a patient is safe after the three-year limit. On theoretical grounds they believed that tapping in these cases was contraindicated in that new paths for lymphatic infection might be opened up. From their statistics, however, the authors do not find this hypothesis to be borne out by the facts; nevertheless they think it is a procedure to be avoided. Nearly every case gave a history of trauma, but this is not important in the etiology.

3. Value of Salvarsan.—C. M. Smith concludes that the early hope of curing syphilis with a single massive injection of salvarsan has not been realized. It is a potent remedy in healing all manifestations on the skin or mucous membranes. It is more efficacious than mercury in changing a positive to a negative Wassermann reaction. Its prompt action on early moist lesions has a decided effect in limiting the spread of contagion. The early fears of damage to the cranial nerves appear to be groundless. When given in proper amounts at proper intervals salvarsan is practically devoid of danger.

1. Glaucoma.—W. Reber, in discussing the treatment of the eye itself, in this condition, states that the ophthalmic world is divided into two camps, those who contend that operation offers the best chance for the preservation of sight, and those who maintain that treatment with miotics promises the patient some degree of vision quite as long as any operative procedure. To the author the truth appears as usual to lie between these two extremes. So long as a patient under thoroughgoing elimination and miotics in the eye can maintain a useful degree of vision without increase of intraocular tension or cupping of the optic nerve head and reduction of the visual fields, we would be slow to recommend operation. But if in spite of such general and local treatment the vision continues to fall off to a point where reading of good-sized print becomes impossible and the visual field suffers with deepening of the optic nerve cup, we would urge operation at such a time with all the earnestness at our command. One's choice of operation would be sclerocorneal trephining, which seems a much safer operation. As to the proper method of miotic medication, the author states that beginning with one grain to the ounce of pilocarpine and one-half grain to the ounce of eserine, the pilocarpine is used three times during the day and the eserine at bedtime. From time to time the strength of the miotic is increased, enough being used to keep the pupils well contracted. The solutions should be freshly prepared, at least once in two weeks, and filtered each time. The patient is cautioned to keep the dropper clean lest the solution become contaminated. Unless the patient is willing to cooperate with the physician at every point, this form of treatment will often fail. Obviously, therefore, the miotic treatment produces its best results in private patients and frequently fails in hospital and dispensary patients, a large proportion of whom necessarily would come to operation. Ocular massage is sometimes of great help in this peculiar class of cases. In the chronic form of the disorder the fullest cooperation of the general practitioner and the special practitioner is demanded. If the patients will submit to thorough elimination and conscientiously adhere to the miotic treatment they may often escape operation for many years and sometimes altogether. If patients will allow themselves to be rightly guided in the way of proper living by their medical advisers many cases of chronic noninflammatory glaucoma may in future be prevented.

2. Glioma of the Cauda Equina.—W. M. Leszynsky reports a case of this condition in a woman forty-nine years of age. The history of unilateral root pains of several years' duration, followed by a similar condition on the opposite side, and later by signs of compression such as bilateral foot drop, and ultimately complete paraplegia, etc., were all indicative of a neoplasm, involving principally the cauda equina. It was assumed that the adjacent lumbosacral cord, also the thoracic portion of the cord, were secondarily affected. Operation was advised, and this was performed, December 22, 1911, by C. A. Elsberg. Death occurred from exhaustion March 18, 1912.

1. The Phenomena of Infection.—V. C. Vaughan contradicts Doerr's statement that bacteria have a relatively simple molecular structure and asserts that all infecting agents are living proteins capable of growth and multiplication. He states that their pathogenicity depends on their ability to grow in the body, their rapid multiplication and wide distribution leading to acute systemic disease, and their slow or localized growth leading to chronic or localized disease. A new ferment may be formed or an old one modified by which the body

is protected against certain diseases, such as smallpox. The author is convinced that infective bacteria contain an intracellular poison common to all proteins, and that the poison which kills in all infectious diseases is the same; but the specificity of the bacteria lies in the non-poisonous groups, and the symptoms differ according to the organ or tissue in which the poison is liberated through the splitting up of the virus, which cleavage is due to a specific ferment. By means of animal experimentation the author found that the bad results of an infective disease are determined by the rapidity of the growth of the virus and the amount of accumulation of foreign protein at the time of effective sensitization. As Gamaléia concluded, twenty-five years ago, the febrile process is the result of the reaction of the organism against the bacteria and not of bacterial action. Vaughan has produced experimentally in animals, acute, remittent, intermittent and continued fevers and their accompaniments. Protein fever, which includes practically all clinical fevers, is a result of parenteral protein digestion, in which the animal cells furnish the ferment. The human being is immune to most bacteria and protozoa because they are destroyed, as soon as they enter the body, by the nonspecific proteolytic ferments probably secreted by the leucocytes, and normally in the blood and tissues. A protein not thus disposed of is deposited in some tissue or organ for which it has a predilection, such as the pneumococcus in the lungs. The time of development varies with the sensitizing protein. Solution of the problems of the conditions affecting a fever awaits further research. The author gives the evidence for and against this theory, drawing from the facts presented the conclusion that, although the exact chemical structure of the poison produced by the disruption of the protein molecule by chemical agents is not known, and though it has not been proved that the poison formed *in vitro* is identical with that formed *in vivo*, yet they are closely related, as is inferred from their physiological action. He warns that, since every unbroken protein contains a highly poisonous group, serum and vaccine therapy should be carefully used. He protests against classifying toxins and anaphylactogens together as "antigens." The fact that tuberculin, according to most investigators, either does not sensitize or does so imperfectly raises a question as to its usefulness in therapeusis, though it is an excellent diagnostic agent and through the tolerance established by it to the tuberculopoison should be used unless the more completely isolated poison is preferable.

2. **Gastric Tetany.**—W. L. Rodman reports a typical case of duodenal ulcer on which a no-loop posterior gastrojejunostomy was done. For ten days the convalescence was uneventful. After walking about the hospital and feeling very well on the tenth day, the patient had a restless night and suffered a recurrence of the spasm of the stomach that had troubled him before the operation. On the morning of the eleventh day he had a convulsion, beginning at the fingers and progressing to the extremities, but not involving the trunk. The patient's mind was clear throughout the attack, but he complained of a "terrible weakness" and his heart action was greatly quickened and respiration embarrassed. About the same time the next day he had another similar convulsion, but more severe, and extending to the abdominal muscles. The characteristic feature of this convulsion and of a later one was the drawing of the face to the left side and the rolling up of the eyeball. He had five convulsions in four days and then they ceased. Their disappearance was thought to be due to the frequent and copious lavage. The patient made a good recovery, left the hospital after thirty-one days and has continued well since. The interesting point is the late appearance of the tetany symptoms. In all the cases observed there has been great dilatation of the stomach, and in most cases from benign obstruction of the pylorus. While no theories of its causation are entirely satisfactory, Rodman seems to favor that of Mayo Robson that it is due to the absorption of the stagnant contents of a dilated stomach poisoning the nerve centers. Medical treatment of these cases is practically a failure, the great majority of the patients die. Surgical treatment is usually successful. This consists in a drainage operation, to relieve the distention. Frequent and thorough lavage of the stomach is beneficial in lessening the severity of the spasms. The author thinks a too optimistic view of the surgery may be obtained and that nothing is likely to give relief in the very severe cases in which the musculature is generally involved. His case shows that gastric lavage with rather full doses of antispasmodics may improve matters. Careful attention to diet also is advised. Buttermilk was the ideal nourishment in the case reported.

4. **Chronic Arthritis.**—L. S. Milne speaks of the confusion that exists in the nomenclature of the chronic arthritic conditions on account of the multiplicity of types which they may assume. The most simple type is that observed in old age, when the joints become stiff and painful from the participation of the cartilage in the general atrophy. This may occur independently of arteriosclerosis and as commonly in women as in men. There are no inflammatory changes associated with the process. True arthritis is an inflammatory process and the same cause may give rise to vastly different forms, and vice versa. It occurs in the course of numerous affections. In rheumatism there is a rapid transient involvement of the joints. A great variety of organisms, gonococci, streptococci, staphylococci, occasionally pneumococci, typhoid bacilli, and the colon bacilli may present arthritis as their most prominent clinical symptom. The author believes that defects in the metabolism are not proved and the digestive disturbances which accompany arthritis may also be due to its infecting cause. Arteriosclerosis is not proved as a cause and there are no conclusive proofs that deprivation of lime salts is a factor. In studying the pathology of arthritis the author has found much the same changes as can be produced experimentally in animals, the intensity and duration of its action being responsible for the clinical types. Sometimes a real osteoarthritis is produced in addition to the synovitis and damage to the cartilage. If at any time the infecting process can be discontinued the progress may be arrested. One must not assume too quickly when an infected focus is found that it is always the sole or chief factor, but all possible sources of infection should be searched for. It is remarkable how many cases are due to pyorrhea and caused by certain cocci of low pathogenicity. In cases in which there is no pyorrhea, streptococci may sometimes be demonstrated in the urine or feces. Autovaccination will often improve and limit the morbid process. A good deal can be done in cases without any signs of infected process and when they are stationary though with much deformity considerable can be done with orthopedic measures.

6. **Serodiagnosis of Cancer.**—C. F. Ball states that the results obtained from the Abderhalden ferment test indicate that it has special value in the diagnosis of cancer as in that of pregnancy. These results seem to demonstrate that there is a similar ferment produced in cancer and that it is quite as specific. Vaughan's views are quoted: According to him, one may obtain positive cancer reaction in two classes of cases: "First, occasionally clinically normal persons who have at some time or other possessed a cancer invasion which had been entirely eradicated, and, secondly, all cases possessing even the slightest malignant tumor formation. The latter

class may rightfully be divided into two subdivisions—those suspiciously malignant and those clinically malignant." The author gives a table of fifty-one serum examinations classified as clinically malignant, suspiciously malignant, and clinically nonmalignant. In the first all reactions were positive. In the second class twenty of the twenty-eight cases were positive and have been verified by subsequent examinations, by operation, microscope, roentgenogram or definite history. The test was erroneous in two cases and two of the remaining cases are developing suspicious symptoms. In none of the negative cases have suspicious symptoms developed. In sixteen nonclinically malignant, four were positive, but these were in women in advanced pregnancy, and in each cancer the cancer protein was obtained from a cancer of the uterus. The author gives the findings with pregnant serums used as controls. Eleven nonpregnant women reacted positively and six of the suspected pregnant cases also. The single negative reaction in this group was in a woman with a thickened parietal peritoneum. There were two errors in these other cases which the author attributes to the aminoacids of digestion. Since these errors he has taken the blood for diagnostic purposes, as a rule, on an empty stomach. The positive findings in persons not known to be pregnant all occurred in actual or suspected cancer cases. The author's work has impressed him with two sources of error in the use of the Abderhalden test with the usual uriometer jar or large test tube as an improvised dialyzing apparatus. One is the bacterial contamination of the thimble and its contents when filling the thimble outside the dialyzing chamber. The second and more serious possible error is of getting a drop or so of the blood-serum or a speck or two of the protein material on the outside wall of the dialyzing thimble.

**9. Retroversion of the Uterus and the Dorsal Position in the Puerperium.**—W. C. Gayler, after noticing the common lack of mention of the subject of posterior displacements of the uterus occurring without being caused by obstetrical injuries, says that a very few gynecologists are now adding a fourth cause, namely, the dorsal position during the puerperium. The uterus after delivery is more freely movable than at any other time and is large and heavy. It occurred to the author in delivering a woman who had previously had the round ligaments shortened for retroversion that it would be worth while not to put them under strain after delivery. He asks, "Are we ever justified in putting the recently delivered woman in the dorsal position? The uterus is then larger and heavier than at any time during the life of a woman, excepting before delivery, when a posterior position is impossible. The ligaments have not undergone involution and cannot support the uterus. The normal bladder irritability is usually lacking for several days, often causing unsuspected bladder distention. An overdistended bladder, more than anything else, will tend to push a uterus out of position. In short, it would seem that the dorsal position during the puerperium is the ideal condition for the production of retroversio uteri. There occur: (1) Temporary weakened ligaments; (2) lack of any but ligamentary support; (3) exceedingly heavy and freely movable uterus. Practically all the textbooks on obstetrics ignore the position during the puerperium period, but some of the authors to whom the author has mentioned the subject promised to include it in future editions. The author believes that the dorsal position should be avoided unless proper drainage of the lochial discharge should demand it.

### Berliner klinische Wochenschrift.

*February 2 and 9, 1914.*

**Treatment of Cancer by Roentgen Rays, Radium, and Mesothorium.**—In this number of the *Wochenschrift* we find a number of articles on the above subjects. Bumm gives some very recent experiences on radiation of uterine cancer by radium and mesothorium, with a word on the use of *x*-rays. These results are obtained with the greatest difficulties. Admitting that it is the future alone which must determine whether radiation will be our chief reliance in the treatment of malignancy, the rôle of a prophet is under any circumstance a thankless one. At the present time we can state positively that cancers 3 cm. deep can be destroyed by radiation. It is not unlikely that cancers a few more cm. in depth may be destroyed as a result of improved technique. All this, however, can already be done with the knife. The author finds notes of ten cases, in which radical operation was either contraindicated outright or would have caused prohibitive functional disability, in which radiation had caused a complete cure. Many diagrammatic figures are given which show how completely mesothorium has destroyed cancer of the cervix with beginning invasion of the parametrium. Warnekros takes up the subject where it was left by Bumm, who introduced at the close the subject of Roentgen therapy. His title is Roentgen technique of radiation of cancer. The point of greatest value is deep radiation over the lower abdomen in the attempt to reach cancer of the cervix. By means of an apparatus in which deep action is secured without damage, Bumm has cured five cases of cervical cancer with Roentgen rays alone. Numerous other cures or near cures have been made in cancers of the pelvic organs and breasts. In so-called near cures the cases were beyond the reach of the knife. Warnekros' article is devoted almost solely to a description of his deep radiation apparatus and its mode of use. Lazarus writes on the "present condition and aims of radium-mesothorium therapy." The paper is a technical one only, in which are considered many different elements. A sketch illustrates radiopuncture and tunnel crossfire, in which three tubes (gradium or mesothorium) are present intratumorally at certain levels in such a manner that every portion of the tumor mass is thoroughly penetrated with the rays. The practical portion of Lazarus' article will appear in a subsequent number of the *Wochenschrift*. Pinkuss now gives some of his latest experience with mesothorium radiation in cancer. After two years' experience he looks forward with great hope to the permanent adoption of mesothorium and radium therapy. This hope is bound up wholly with technical evolution, as no new basic principles are yet under consideration. There is so much evident room for technical improvements that these must be gradually acquired. These include such subjects as filter material, concentration and arrangement of radioactive substances, dosage, duration of exposure, etc. Finally from Czerny's Cancer Research Institute Fränkel and Gumpertz dwell on an allied topic, to wit: the action of thorium *x*-injections upon the agglutinins of the blood—since thorium has often been accused of behaving inimically in the blood. In animal experiment it was found that despite the destructive action in the blood resulting from large doses the agglutinins showed normal values in some animals, but that in general the formation of agglutinins was injured in the same degree as are the leucocytes.

**Local Diagnosis of Spinal Cord Tumors.**—Söderbergh sums up his study as follows: In the preceding lines I have meant to give but a brief review of certain problems in localization which has been forced upon me by the analysis of several cases of tumors. The therapeutic results of operations are touched upon only *en passant*, and may at the first glimpse seem to be little encouraging. If, however, one looks more deeply he may derive the very opposite impression. Among the cases which ran an unfortunate course was one of multiple

tumors seated on the anterior aspect of the cord; another a tumor in the uppermost cervical region, likewise seated chiefly on the anterior aspect and firmly attached to the dura. Both of these were from the first of most dubious prognosis. On the other hand, two cases which terminated successfully were of a sort which seldom recover under operation. One was seated at the highest portion of the cervical region, while the other was a bony tumor of the cauda.

**Status and Newest Aims of Radium-Mesothorium Therapy.**—Lazarus concludes an article on this subject as follows: Among the newest aims of the form of treatment are the following: (1) The determination of that quantity of nervous energy required for the acquisition of a definite physiological effect upon individual kinds of tissue and individual depths of the same, as well as the manner by which we can convey this exactly measurable amount of energy to the tissues concerned and to these alone. (2) The construction of an artificial energy transformer by which the change from electric to biological energy shall secure to the latter a strongly active radiant energy of medium amplitude and greatest possible absorption in the interior of the body without the hitherto greatly to be avoided near and remote dangers. It is not improbable that the future will succeed in the artificial production of periodical ether disturbances which closely resemble y-rays. (3) The study of rayed tissues in respect to the chemical transformations which take place within individual cells—reactions, oxidations, fermentative katabolic processes.

**Mesenteric Vein Thrombosis in Phlebosclerosis of the Portal Vein.**—Geppert and Siegfried report a case in which the portal vein sclerosis pursued a latent course. Cases of phlebosclerosis have been reported by twenty-four authors. Some of these cases were believed to have originated from thrombosis of the portal vein. The author believes that genuine phlebosclerosis begins with the known alterations in the wall of the vessel. Among the causes adduced for such changes, syphilis and traumatism must be excluded despite high authority to the contrary. In the severest cases spots of calcification of the intima and extensive ossification of the media are present in such a degree that a calcified and ossified tibial artery is paralleled. In every case of phlebosclerosis thrombosis of the mesenteric vein is sooner or later added, death then occurring from collapse.

---

### Deutsche medizinische Wochenschrift.

*January 29 and February 5, 1914.*

**Therapia Sterilisans in Trypanosome Diseases.**—Kolle, Hartoch and Schürmann have been using for this purpose the trioxide of antimony. Intravenous injection of large animals is practicable. At first with intramuscular injection, local irritation and abscess formation resulted, but by the intravenous method it was found possible to sterilize small animals. In dogs with dourine it was found necessary to use inunctions of synthetics containing antimony in addition to intravenous injections. Before resorting to the use of antimony trioxide the authors succeeded in preparing it in a form nearly related to the colloids. This is doubtless why the substance is sold under a proprietary name.

**Progress in Pharmacotherapy During 1913.**—Cloetta refers first to the revived interest in calcium. Bread containing the latter is made and this should suffice to guarantee to the body its daily requirement. Calcium has gained ground as a remedy for hay fever. It has been combined with ichthyol and injected for tuberculosis. Casein calcium added to dilute cow's milk seems equal to albumin milk in infant feeding. The combination of bromine with calcium should be, and is, of value in epilepsy, because the latter tends to depress nervous excitability as well as the former. Atropine has been found of value in seasickness, and has been termed the natural remedy, 1 milligram of the sulphate to be given, and if necessary, repeated. Many drugs cited are by no means new, and do not belong here. Certain old ones acquire new value; thus American wormseed has been found of great value in Europe for ankylostomiasis. Opium and morphine retard the action of the stomach, intestine, and colon. Pal has shown that opium contains two groups of alkaloids which behave very differently in the intestines. The first, comprising morphine, codeine, and thebaine stimulate the musculature of the entire intestinal wall, both longitudinal and circular fibers. The second group, comprising narcotine, papaverine, and narceine, exert the opposite or depressing action. Opium itself therefore exhibits a double activity, for while the circular fibers are constricted, the longitudinal ones are relaxed. Papaverine seems to be an ideal depressant in spasm of the stomach and intestines. Among other discoveries in the opium group is the superiority of codeine hydrate to codeine. It has been learned that belladonna (tincture) in somewhat large doses persistently is able to hasten metabolism or at least to reduce weight. Colloid metals (palladium, for example) possess the same property. For certain reasons the above remedies are not likely to come into general use. The former recommendations of pyocyanase for local use in infectious anginas has been revived by the introduction of another preparation made from a culture of the *B. pyocyancus*. This did better work than 15 others in a test made for the best local treatment of 480 cases of agina.

**"Innocent" Diabetes of Children.**—Salomon uses this expression to designate a form of diabetes in childhood differing radically from the ordinary severe types. This may be seen in two or more children of a family (familial glycosuria). Neurotic inheritance may be present. The amount of sugar excreted is small; much smaller than in true juvenile diabetes. As a rule there is no increase in the amount of blood sugar. There is no tendency of the disease to progress, despite the growth of the subjects. In a carbohydrate-free diet it is common to see an increased excretion of acetone, which disappears rapidly when carbohydrates are added to the diet. The patients as a rule feel well and do not know that anything ails them, aside from certain petty nervous disturbances. The sugar in the urine of an infant may cause a sugar exanthem on the thighs, etc. Both this mild and the severe type may coexist in one subject (diplomellituria). Many children with this affection have been condemned to death by physicians who know nothing of "innocent" diabetes.

**Ostitis Fibrosa After Typhoid Fever.**—Wolz dates our knowledge of this lesion back to 1880, when French authors began to ascribe all kinds of bone lesions to the typhoid bacillus. The reverse conception that typhoid may be complicated or followed by periostitis of the tibia especially is of course much older. We now speak of typhoid diseases of bones as we do of tuberculosis or syphilis of the same tissue. The number of individual lesions produced by typhoid comprises most of those known to exist under other conditions. The typical lesion is commonly regarded as a circumscribed osteoperiostitis. The bacilli are known to lie latent in the bones (ribs for example) for many years. It has been shown that during the fever the bacilli enter the interior of the various bones and at times produce odd symptoms quite early in the fever—for example torticollis or lumbago, due actually to vertebral disease.

## Insurance Medicine.

The Curve of Mortality.—Life insurance companies are to-day analyzing their mortality experience among many groups of insured risks to an extent never before undertaken. Mr. Virgil M. Kime, Actuary American Central Life Insurance Company, Indianapolis, Ind., shows that when the results of the medico-actuarial mortality investigation in connection with certain medical impairments and certain occupations are published we shall have available a body of data of immense value in guiding our selection of risks. To be trustworthy, the mortality rates on which we base our calculations must be those derived from an experience among lives similar with respect to health, climate, occupation, and environment to those we expect to insure. A variation in either of the factors mentioned may mean a variation in the rate of mortality experienced. A mortality table suited to our use must be derived from an experience among standard insured lives, as these are, in general, better in their prospect of longevity than those of the general population, due largely to elimination of the industrial grades and to the presence of medical selection. The crude rates of mortality on which a mortality table is based, if derived from an experience among insured lives, are obtained by bringing together at each particular age or at each age and duration of policy, the number exposed to risk of death and the number dying, the latter being divided by the former. Depending upon the data from which they are derived, mortality tables may be divided into select, aggregate or ultimate. A select mortality table classifies the rates of mortality both by attained age and by duration of policy, thereby taking into consideration the effect of selection. An aggregate table shows the mortality by attained ages alone based on all the data under consideration regardless of the duration of the policies. Strictly speaking, an ultimate table is one showing the rates of mortality by attained ages, eliminating the experience during the period selection is effective, this period being dependent upon the nature of the selection effected as well as on the ages of the risks. What are usually termed ultimate tables are formed by eliminating from the experience data based on a specified number of years following issue, usually either five or ten. This is more correctly called a truncated table. Theoretically, and excluding the expense of acquiring the business, a select table would be most satisfactory as a basis for premium computations and reserve calculations, since each group would stand by itself and the premiums would provide for the mortality to be expected. An aggregate table would not be proper for such a basis of calculations, since the rates of mortality depend largely upon the relative proportions of new and of old business, and the premiums derived therefrom would be unsafe. Ultimate tables are the best for all practical purposes. The rates of mortality derived are safe, and the premiums adequate. In every mortality table there occur certain irregularities in the crude mortality rate which must be removed. It is customary to smooth out a table before the results are used for actual calculation. To do this a curve is drawn plotting out the data for the various ages; then a smooth curve is superimposed over the original curve, eliminating its irregularities and the result used as fairly representing the general experience set forth. Graduations may be effected by mathematical formulæ.

The first American mortality table was constructed in 1853 by Professor Gill of the Mutual Life and bears his name. The next, the American Experience Table, was formed by Sheppard Hoffman, also of the Mutual Life, in 1858, and is the one in most common use. It is an example of an ultimate table, in that the mortality experience for the first five years has not been included. The Medico-Actuarial Table is somewhat newer and also in common use. Mortality tables are also based on mortality experience by ages, by kinds, by amounts, and by years. The Medico-Actuarial Table is evidence of the fact, as shown in Mr. Kime's article, that it agrees with other statistics that mortality, particularly at the younger ages, has materially improved within the last twenty to twenty-five years. In studying mortality tables, the composition of the business of various companies must be taken into consideration, as a company writing a predominating volume of ordinary insurance will have a higher mortality than one writing principally endowments.—Medical Section, American Life Convention.

**The Accident Toll of the Surgeon.**—Feilchenfeld considers the medical man as to the hazard of his calling. The extrahazardous risks make up from 1½ per cent. to 2 per cent. of the ordinary toll, according to the special activity of the insured. Operators who in the carrying out of operations run a risk of slight injury with possible infection from suppurative processes and infected wounds come under the 2 per cent. danger class. Here belong surgeons, gynecologists, and pathological anatomists. Within the past few years this hazard has become notably lessened by the adoption of rubber gloves by all these practitioners. Injuries and infection occur much more infrequently. Hence the demand would be justified in taking account of this circumstance by reducing the surgeon's risk to that of the practitioner of ordinary professional hazard of 1½. For by reason of the greater sparing of the hands in substituting the glove for the frequent washing with antiseptics, the former eczemas, boils, etc., are less frequently encountered and are less liable to suppurate and transmit suppuration. All such affections rate as ordinary accidents. The author calls attention to the present infrequency of these injuries of the hands. No doubt this viewpoint could be confirmed by statistics. If this is the case then a reduction of tolls should follow.—*Zeitschrift für Versicherungsmedizin*, July, 1913.

**Insurance for Women—What it Usually Means.**—E. J. Spratling, Medical Director Majestic Life and Commercial Life, states that the matter of issuing policies to women simply hinges on the motives for taking insurance. If the motive could be obtained with certainty, the intuition of the examiner or medical director could be depended upon in the majority of cases, to decide whether or not to issue the policy, but the motive is generally the part concealed. Even the most suspicious medical directors get caught unmercifully in handling women risks. The speculative element is too potent in the case of women, consequently the motive for deception is nearly always present when women are applying for insurance.—American Life Convention, Medical Section.

# Book Reviews.

MODERN MEDICINE, ITS THEORY AND PRACTICE. In Original Contributions by American and Foreign Authors. Edited by Sir WILLIAM OSLER, Bart, M.D., F.R.S., Regius Professor of Medicine in Oxford University, England; Hon. Professor of Medicine in the Johns Hopkins University, Baltimore; formerly Professor of Clinical Medicine in the University of Pennsylvania, Philadelphia, and of the Institutes of Medicine in McGill University, Montreal, Canada; and THOMAS MCCRAE, M.D., Professor of Medicine in the Jefferson Medical College, Philadelphia; Fellow of the Royal College of Physicians, London; formerly Associate Professor of Medicine, the Johns Hopkins University. Vol. I. Bacterial Diseases: Diseases of doubtful or unknown etiology, non-bacterial fungus infections, the mycoses. Second Edition; thoroughly revised; illustrated. Philadelphia and New York: Lea & Febiger, 1913.

IT is six years since the first edition of the theory and practice of medicine, edited by Sir William Osler and Dr. Thomas McCrae, was published. The work has proved valuable and popular and a second edition is welcome. The new edition has been thoroughly revised; some matter which appeared in the first edition has been omitted, while some fresh material has been added. There are new sections on pellagra, beriberi, trypanosomiasis, Malta fever, and electrical diagnosis in cardiac disease. All the papers in the new edition have been greatly condensed, especially in the etiological and pathological portions. Owing to this condensation, increased size of page and by augmenting the number of pages in each volume the number of volumes has been reduced from seven to five. In the first volume the greater part of the book is taken up with a consideration of the bacterial diseases. Three chapters are devoted to tuberculosis, that on the pathology of the disease by Dr. W. G. MacCallum of New York being an excellently clear exposition of that branch of the subject. Dr. E. Farquhar Buzzard of London, England, gives a good account of acute poliomyelitis. Dr. Rufus Cole deals with gonococcus infection and Dr. Thomas D. Coleman of New York with Dengue. Rabies is discussed from all standpoints by Dr. Mazyck P. Ravenel.

Perhaps the most important contribution to Volume I is that by Dr. Frederick J. Poynton of London on rheumatic fever. Together with Dr. Paine the writer of the article has done a good deal of original work with regard to the etiology of rheumatic fever. They have discovered a microbe which they have called *Diplococcus rheumaticus*, which they claim to be the essential factor in the production of rheumatism.

Dr. James Homer Wright has contributed a chapter on the non-bacterial fungus infections. The first volume is in line with the advances which have been made within recent years in scientific medicine. The volume is well printed and illustrated, the type is clear, and the illustrations aptly serve to explain and emphasize the text, a point of importance in works of this description.

MEDICAL AND SANITARY INSPECTION OF SCHOOLS. For the Health Officer, the Physician, the Nurse, and the Teacher. By S. W. NEWMAYER, A.B., M.D., in charge of Division of Child Hygiene, Bureau of Health, Philadelphia. Illustrated with 71 engravings and 14 full-page plates; price $2.50. Philadelphia and New York: Lea & Febiger, 1913.

THE medical inspection of school children has attained an extraordinary elaborateness of supervision, organization, and scope. Many difficult problems pertaining to the duties of school nurses, the correction of the physical defects of school children, the prevention of contagion, etc., have arisen, and have been solved by the large cities that have undertaken school medical inspection on a large scale. The author of this volume has studied this subject in its myriad phases and has succeeded in presenting a comprehensive and systematic work not only on school inspection but also on school hygiene and sanitation. The book is eminently practical, describing methods of administration and inspection that are in actual use. It contains a large number of illustrations, including views of classrooms, playgrounds, methods of inspection, etc. The sections dealing with the administration of medical inspection, with the keeping of records, the relation of schools, hospitals, and clinics, the construction of school buildings, and the various physical defects and infectious diseases found in school children are particularly well written.

A TEXTBOOK OF PHYSIOLOGY. For Medical Students and Physicians. By WILLIAM H. HOWELL, Ph.D., M.D., Sc.D., LL.D.; Professor of Physiology in the Johns Hopkins University, Baltimore. Fifth Edition; thoroughly revised; price $4.00. Philadelphia and London: W. B. Saunders Company, 1913.

THE advances in modern medicine are closely associated with the growth of the knowledge of physiology. He who has not consulted a textbook on the latter science since his student days, one or two decades ago, and who now scans the pages of a volume such as the one under review, is apt to marvel at the extraordinary additions that have been made to the knowledge of physiology within the past decade. These additions are conspicuously manifest in such subjects as the chemistry of the proteins, the physiology of digestion, the mechanics of the heartbeat, the localization of functions in the brain, etc. All of these advances are set forth in the present edition, which in this and in other respects maintains the high standard which it has achieved as an authoritative textbook suitable for study and for reference, both to the student and to the physician.

LEITFADEN DER ERSTEN HILFE; ein Samariterbuch. Von J. LAMBERG, Chefarztstellvertreter der Wiener Freiwilligen Rettungsgesellschaft. Mit 1 farbigen Tafel und 190 zum Teil farbigen Abbildungen im Text. Price 5 marks. Berlin and Vienna: Urban & Schwarzenberg; New York: Rebman Company, 1913.

THIS is an excellent first aid manual written for laymen by one who has had an experience of thirty years in the organization and direction of voluntary first-aid work in the city of Vienna. In the first chapter is described the historical development of first-aid relief. The second chapter deals with the anatomy and physiology of the human body. The next chapter discusses first aid in sudden illness, such subjects being included as fainting spells, epileptic attacks, childbirth in a public place, strangulated hernia, etc. First aid to the injured forms the subject-matter of the fourth chapter. In the fifth chapter the author discusses "technical" first aid, including the rescue of the drowned, the rescue of those who break through ice, the management of the victims of electrical accidents, etc. The transport of the sick is described in Chapter VI. The concluding chapter deals with the nursing of the sick at home. The book is one of the best manuals on first aid that have been written within recent years. It is profusely illustrated and is eminently complete and practical.

AN INTRODUCTION TO THE STUDY OF INFECTION AND IMMUNITY, including chapters on Serum Therapy, Vaccine Therapy, Chemotherapy, and Serum Diagnosis. For Students and Practitioners. By CHARLES E. SIMON, B.A., M.D., Professor of Clinical Pathology and Experimental Medicine at the College of Physicians and Surgeons; Pathologist of the Union Protestant Infirmary and the Hospital for the Women of Maryland; Clinical Pathologist to the Mercy Hospital of Baltimore, Md. Second Edition. Price $3.25 net. Philadelphia and New York: Lea & Febiger, 1913.

THE second edition of this work appears within a year after the publication of the first edition. This is gratifying evidence of a widespread desire to become acquainted with this important subject. On this account it seems rather unfortunate that the publishers have seen fit to present this material in such an expensive form. The subject of immunity is changing with tremendous rapidity and it would seem that the needs of the profession would best be served by frequent and cheap editions so that the revisions could be purchased as they appear without great expense. In this respect the German publishers are far ahead of those in this country.

The second edition has been amplified by the insertion of sections on auto- and normal serum therapy, on the chemotherapy of pneumococcus infections, and of cancer, and on the serodiagnosis of pregnancy. The remainder of the material has undergone sufficient revision so as to bring it into accord with recent investigations. The discussion of anaphylaxis is especially complete and shows very well the unsettled state of our knowledge in this branch of the subject. The style is easy and attractive and the book should find a place in the library of every physician.

# Society Reports.

## WESTERN SURGICAL ASSOCIATION.

*Twenty-third Annual Meeting, Held at St. Louis, December 19 and 20, 1913.*

THE PRESIDENT, DR. JABEZ N. JACKSON, OF KANSAS CITY, MO., IN THE CHAIR.

**Tuberculous Hip-Joint Disease and Its Treatment with Bismuth Paste.**—Dr. EMIL G. BECK of Chicago read a paper on this subject in which he reported 102 cases. The bismuth paste had been employed for diagnostic and for therapeutic purposes, as well as for the treatment of cold abscesses. He demonstrated three unique cases of hip-joint disease. Examples like these explained to a degree why surgical operations for these chronic suppurating sinuses often failed. A glance at the radiographs which represented injected sinuses taught us how irrational it was to attempt a dissection of tortuous sinuses which led into an inaccessible region. In the light of these pictures the probing of a sinus would not appeal to those who wished to be consistent. He had made the following general observations: 1. He had found that hip-joint disease in its incipient stage was too frequently diagnosed as rheumatism. Two-thirds of the cases gave the history of having been treated in the beginning for rheumatism or sciatica. 2. He had further noted that when the disease had progressed to the stage of abscess formation, incision and drainage was, as a rule, the form of treatment, a method which was now generally condemned. 3. He noted also that sacral tuberculosis or that of the sacroiliac joint was frequently taken for hip-joint disease. He had met with five such cases. The reason for this mistake was explained by the similarity of the swelling and contractures of the limb on the affected side, which he found in hip-joint cases. He had noted that when a patient who for years could not carry his weight on diseased limbs, on account of acute pain in the joint, and was obliged to use crutches, could, after the joint was closed, walk without pain, and he had in most instances allowed the patients to discard the crutches. The prevention of bismuth poisoning consisted in not allowing large quantities of the paste to remain in the body for absorption. Should the symptoms appear, the paste must be removed by washing out the cavity with warm olive oil. The sterile oil was injected and retained for from twelve to twenty-four hours, in order to produce an emulsion, which should be withdrawn by means of suction. After its removal all symptoms would promptly disappear. Scraping out the paste with a scoop was a dangerous procedure because it opened fresh channels for absorption.

Dr. J. W. COKENOWER of Des Moines, Iowa, said he had tried carbolic acid, formaldehyde, iodoform, etc., along the line of treatment of injections, and failed. When bismuth paste was brought forward, he tried it and failed. He also got bismuth paste poisoning in some cases. The reason for the poisoning was this: in a case of cold abscess he made too large an incision. There seemed to be considerable necrotic tissue. In curetting he exposed new tissue, injected the paste, and in the place where he left it raw the paste was absorbed. To obviate his mistake, he injected olive oil, filled the wound, allowed it to remain twenty-four hours, then took a suction pump, pumped out the paste, and saved the patient. One should make a small incision in these cases, the pus being sterile, injected with bismuth paste, and then its presence would stimulate leucocytes, dispense with the phagocytes, and bring about a prolification of tissue, and if the injection was made properly, one injection was sufficient.

Dr. WILLIAM T. REYNOLDS of Kansas City, Mo., asked Dr. Beck to explain the process of repair, or what brought about the cure.

Dr. BECK, in reply, thought leucocytosis was the underlying factor, and this was probably generated from the subnitrate of bismuth. He did not think it was absolutely essential to use bismuth. There were other substances that might do, but so far he had found no good substitute, and although he had tried ten or fifteen substances, none had proved satisfactory.

**The Use of the Wire Clamp in Operations for Goiter.**—Dr. LEONARD FREEMAN of Denver, Col., said that the wire clamp had a number of advantages: 1. It might be adjusted to almost any goiter—by bending the wires if required, although this was seldom necessary. 2. The control of hemorrhage nearly always was perfect, so that the gland might be sliced off beyond the clamp with absolute confidence. 3. The tissues were not crushed—simply constricted as in the use of a tourniquet, which was of importance in Graves' disease at least. 4. There was no danger to the recurrent laryngeal nerves or to the parathyroids. Even if they should be caught in the grasp of the wires, which was unlikely, the compression would not be great enough to do them permanent injury. 5. There was no chance of the wires slipping from the stump after resecting the gland, because they were held in place by the loops passing through the base of the lobe. 6. The wires were much narrower than the blades of a pair of forceps and hence took up less room. The author used this method in some twenty goiters of various kinds, where it seemed to be indicated. The operations proceeded easily, safely, without anxiety, and there were no fatalities.

**Parosteal Callus; the So-Called Myositis Ossificans Traumatica.**—Dr. OLIVER J. FAY of Des Moines reported six cases of traumatic intramuscular ossification; in four cases the brachialis anticus was the muscle involved, in two the vastus medius. In two cases the ossification followed a dislocation of the elbow, in three others a contusion was the determining factor, while in the remaining case there had probably been a rupture of the muscle. The youngest patient was sixteen, the oldest fifty. None of the four theories advanced to explain the pathogenesis of these intramuscular bone formations (the hemic theory, the theory of aberrant sesamoid bones, the theory of periosteal detachment or dissemination, and the theory of ossifying myositis) was entirely satisfactory. The first two had found but few supporters; the third did not explain muscle ossification in muscles not overlying the bone, while the fourth, in so far as it assumed a hematogenous infection lacked clinical evidence. Histologically, the bone mass was found to bear a close resemblance to the callus of fractures; the whole picture was that of a reparative process, the damaged connective tissue cells having temporarily lost their differential function and become osteogenetic. Since the term myositis ossificans traumatica emphasized the inflammatory rather than the reparative nature of the ossification the author preferred the appellation *parosteal callus*. The early symptoms were those of any contusion, but the functional did not keep pace with the objective improvement and an indurated mass became palpable. While the clinical picture and the history of trauma might suggest the presence of a parosteal callus, the radiograph was essential to differential diagnosis. Operation was indicated where there was functional disability or where the parosteal callus interfered with the blood or nerve supply. The prognosis was good unless there was periarticular ossification. An early operation must be radical, and all damaged tissue removed to guard against a recurrence, but better functional results were obtained if the callus was allowed to "ripen." A conservative operation was then possible and the maximum amount of the muscle tissue was saved.

**Subacromial Bursitis.**—Dr. L. W. LITTIG of Davenport, Iowa, stated that the subacromial bursa, as large as the palm of a small hand, and located between the tuberosity of the humerus and the tendon of the supraspinatus below, the overhanging acromion above, had been described as made up of two separate and distinct bursæ, the subacromial and the subdeltoid. Codman, who brought this subject prominently before the profession in 1906, considered a single bursa the more usual condition. Prentiss, basing an opinion on an enormous dissecting room experience, considered this bursa usually multilocular, which might be regarded as evidence of the frequency of bursitis, as the loculi must indicate preceding inflammation followed by more or less "stretched" adhesions. Shoulder joint disability due to inflammation of this bursa was exceedingly common, and usually diagnosed as rheumatism, neuritis, sprain, myositis, etc. Traumatism of one kind or another, as a blow or fall on the shoulder, or general sepsis, was the usual cause of subacromial bursitis. In the acute stage of bursitis the shoulder joint was locked by muscle spasm whenever movement beyond an arc of 10 degrees was attempted. Abduction, and outward and inward rotation were impossible because of muscle spasm and pain. Or the bursa might be distended with fluid, and caught between the tuberosity of the humerus and acromion, thus mechanically limiting abduction. In the second stage adhesions formed between the opposing floor and roof and the above-named movements were limited partly by pain and muscle spasm, but more

efficiently by adhesions. In the third stage movement might be quite free, although abduction and internal and external rotation were more or less limited, depending on the character of the adhesions between the opposing walls of the bursa, or by the bursa distended with fluid. Dawbarn's painful point was of value in making a diagnosis, and consisted of severe pain on pressure just beyond the acromion when the arm was hanging at the side. The painful point disappeared when the arm was raised. When a distended bursa limited abduction a slight rotation outward brought the bursa between the overhanging acromion and the neck of the humerus, in which position the arm could be raised with less difficulty. In the second stage adhesions might be stretched, which was best accomplished by standing on a block of wood, firmly grasping some object, as a crossbar, just within reach, and then stepping to the floor. This cross-bar might be gradually raised perhaps an inch a week, and the range of motion gradually increased. Excision of the bursa might be considered.

**Multiple Exostoses: An Hereditary Affection of the Body Skeleton.**—Dr. Roger T. Vaughan of Chicago stated that all cartilaginous exostoses were congenital in origin, being demonstrable probably at birth, though usually not recognized by patients or clinicians till years later; that the tendency to their formation was hereditary and transmissible; that they were frequently accompanied by other developmental defects of the skeleton, some of which were characteristic of the affection; and that these tumors might be accompanied by congenital defects of other body structures. The fact that cartilaginous exostoses as well as enchondromata represented congenital anomalies of the skeleton had not been generally recognized and accepted until relatively lately. Since these tumors were usually noticed only late in youth, when they attained a considerable size, and since the patients themselves usually considered them an acquired affection, the medical profession had been late in recognizing their congenital origin. Of late years, however, there had been a numher of cases recorded in which these exostoses were noted at or shortly after birth. Multiple cartilaginous exostoses were, as a rule, a harmless affection. The disturbance in the wrist and elbow joints were the most bothersome. A few exostoses might, on account of their location, become very burdensome, but rarely dangerous. Those exostoses which locked the joints might be removed. Neuralgia, paralysis, epilepsy, apoplexy, defective hearing, dystocia in labor and rupture of the uterus, exophthalmos, rupture of the popliteal artery with aneurysm formation, and also malignant degeneration had been described. In view of these severe, even if infrequent, complications, and the considerable and not infrequent deformities occurring in this disease. the undesirability of the intermarriage of members of exostosis families in the light of Mendel's law should be recognized by physicians and eugenists.

Dr. A. A. Law of Minneapolis stated that they had recently found in the Minnesota clinic that it was an absolute impossibility to differentiate these benign conditions in some cases from the extremely malignant osteosarcoma, with a mortality of practically 99 per cent. from metastases. A case in point prompted him to bring up this question. A boy in a football accident was kicked above the left petalla. They saw him a month after the accident, when he had a typical fusiform, non-inflammatory tumor, apparently in connection with or attached to the femur. A series of $x$-rays were taken of the femur, twenty in all. The case was seen by Drs. Mayo and Moore, and others. who were of the opinion that they could not make the differentiation for the simple reason that the clinical picture presented by the $x$-ray was that of osteosarcoma with feathery trabeculæ about the femur. Exploration was finally resorted to, and the tumor found to be inflammatory. There was a degenerating blood clot.

Dr. Arthur E. Hertzler of Kansas City, Mo., said that if Dr. Law would hear in mind that the ray-like processes in ossifying myositis ran parallel to the fascia and muscle fibers, while in periosteal sarcoma the rays were fan-like, extending from the base of the bone in all directions, and not parallel to the muscle fibers, it would assist in the differentiation.

Dr. Emil G. Beck of Chicago had taken different bones and made stereoscopic pictures of them, and through the stereoscope they got very fine points, the three dimensions, and the changes which were on a single $x$-ray picture very diffuse became concentrated. He thought the whole question of pathological specimens, tumors, etc., could be differentiated. They could differentiate a sarcoma from a cyst or inflammatory condition by stereoscopic pictures.

Dr. M. L. Harris of Chicago said that there were two other varieties of the so-called ossifying myositis. First, it was found that practically the traumatic variety developed at the point where the muscle had a broad attachment to the bone or other organs; in other words, where the muscle fibers came into connection with the bone, there was no periosteum which in any way could play a part in the process. Second, and this was very important in the diagnosis of osteosarcoma, this condition never had a distinct individual growth like a tumor. Therefore, they were always differentiated from tumors by the fact that they never showed a characteristic, individual growth like a tumor, always limited, and when once the foundation was laid, they never showed a progressive tendency; they always saw the original outline in the early $x$-ray, and they appeared to enlarge on successive $x$-rays, but the original foundation was practically always laid early, and they did not show a progressive tendency after that point.

Dr. D. S. Fairchild of Des Moines, Iowa, stated that a few days ago a boy, 20 years of age, received an injury to the elbow joint. The nature of the injury was not known. The case had been treated as a fracture; it might have been a dislocation, and the elbow joint was kept in splints for some time. The case was sent to a doctor in the community; an $x$-ray picture was made, and the doctor proposed that something should be done at once to the elbow joint to secure good motion. He operated but the result was not satisfactory. The patient, discovering the several elements in the case, came to Dr. Fairchild of his own accord, and he made the $x$-ray examination as Dr. Fay had shown, which he gave Dr. Fay. In the past, he had had a great deal to do with cases where splinters of bone came off in the accident, and these spiculæ could be felt by the examining finger, if large enought to be felt through the soft parts, but since the advent of the $x$-ray they were able to interpret conditions exactly.

Dr. James F. Percy of Galesburg operated on a woman, now 45 years of age, about ten years ago for an extensive carcinoma of the right breast. She had no signs of recurrence for eight years, and then she returned with pain above the collar-bone and extensive swelling of the right arm. Examination showed that the subclavians were probably being pressed upon by this growth, and the $x$-ray revealed a growth coming from the fourth or fifth dorsal vertebra, going up back of the lung and coming up inside of the collar-bone. He assumed that this was a recurrence in the bone of carcinoma. A surgical friend gave a bad prognosis, saying she would probably not live more than two or three months. This was two years ago. She had had in the neighborhood of 230 $x$-ray treatments. There was no sign of an $x$-ray burn, and at the present time there was almost nothing to be seen of this growth.

**Gas Bacillus Infection.**—Dr. W. D. Haines of Cincinnati, Ohio, spoke of the high mortality of this type of infection and the importance of early recognition and prompt action and referred to the "foamy" liver as one of the constant findings post-mortem. The intestinal tract was one of the normal habitats of the gas bacillus, and invasion of the adjacent cellular structures might take place through ulcer, malignant disease, or perforation. A case was cited wherein an enormous abdominal distension from gas bacillus was mistaken for postoperative dilatation of the stomach. The disease appeared as a local phlegmonous inflammation characterized by extensive exudate and the presence of hydrogen gas in the tissue spaces. Pressure gangrene and profound general toxemia were frequently associated with the clinical manifestations. The period of incubation in one of the cases reported was forty-eight hours; in the second case it could not be determined. The *Bacillus aerogenes capsulatus* was anaerobic; therefore, success in the treatment would depend more upon free exposure of the infected area than upon any form of local or internal medication. The report of two cases, one of infection of the scrotum, and the other of the arm, where recovery followed free incision, concluded the paper.

**President's Address.**—Dr. Jabez N. Jackson of Kansas City, Mo., after referring to the progress that had been made in surgery, took up the question of fee splitting. That was a practice which led to several indictments. (1) It induced family physicians to betray the sacred confidence of their trusting patients and referred them to men who were not the most competent, not those who offered the greatest possibility of

the saving of life, the preservation of health, but to men who paid for the victim. Life risked for money! Was it much worse to take life for money? (2) It lowered the dignity and value of the services of the family physician who was presumably rendering valued services for nothing, and gave a magnified value to surgery which was presumably receiving all. How much more exalted would be the standing of the general practitioner if people were taught to value his services in diagnosis and his responsibility in counseling surgery and recommending a surgeon until they would expect to pay for that service as they would for any other. It should be the privilege of the surgeon to aid the physician openly to secure this just compensation. (3) As a rule, the trusting patient was robbed, paid two fees instead of one, as he supposed. (4) It was the stepping stone by which incompetent men secured business. (5) It penalized honesty in the young surgeon who was capable but must sit idly by and starve while his less competent competitor bought the business. (6) It led to many unnecessary operations with their attendant risk and expense performed merely because the patient could be induced and had the price. In all it was a betrayal of trust, encouraged dishonesty, bred incompetency, and should in short, be held a crime. In conclusion he wished to offer two suggestions for added activity of the society: (1) That an added day of the annual sessions be inaugurated as a permanent feature, devoted to clinics, conducted by Fellows of the society resident at the place of meeting. That was for the purpose of enabling them to become better acquainted with the operative work of their associates. (2) The Clinical Surgical Society several years ago began the plan of a party trip to some of the foreign clinics every alternate year. These trips had been reported as exceptionally profitable and pleasant. Few of the Fellows belonged to the Clinical society. Would it not be equally valuable to them if they could inaugurate a similar custom? The itinerary being varied with each successive trip would in time bring those who went a familiarity with practically all of the work of the world. Such a party would ensure a cordial welcome and an assurance of systematized preparation with a wealth of material so that more could be seen with less expenditure of time than by any other method. That plan should stimulate the breadth of their knowledge and correspondingly the richness of their work.

**Pericolic Membranes, Resulting from Experimentally Produced Coprostasis.**—Dr. Joseph Rilus Eastman of Indianapolis stated that anomalous peritoneal folds, wherever and whenever found, notwithstanding their variations in macro- and microscopic appearance, were with respect to their nature and origin quite closely related. The frequency of anomalous pericolic folds in the fetus, and the fact of their very common presence in young children indicate that whatever the fundamental pathological process which causes them might be, this process frequently became operative in embryonal life. However, the actual manner of the formation of such membranes was not made clear by such observations. It was probable that in many instances at least the same pathology led to pericolic membrane formation in fetus and adult, and that reaction to irritation, with or without consequent fusion or adhesion, underlies anomalous pericolic membrane formation in practically all cases. He had experimentally produced pericolic membranes in rabbits by inducing a low grade plastic peritonitis. The mild adhesive peritonitis occurred as the result of the plugging of the large intestine with its own contents. Extreme coprostasis was induced by intermittent ligation of the anus and administration of morphine over a period varying from two weeks to three months. In this manner pericolic membranes, or membraniform adhesions about the colon were produced in eleven rabbits. Care was taken not to confuse the long flowing mesenteries of the rabbits with membraniform adhesions. As in other quadrupeds, the mesenteries of the rabbits were luxuriantly developed, a single mesentery in some cases enveloping and supporting several intestines. The membranous adhesions which were attributed to the artificially induced plastic peritonitis occurred in cases in which the intestines over extensive areas were held together by plastic lymph. The membranes were brought to view by separating the intestine at the site of imperfectly organized adhesions. From these observations it appeared that extensive membraniform adhesions might result from extreme coprostasis, and this was exactly as we should expect, for we knew that incarceration of hernia and other forms of obstruction of the intestinal lumen, without visible lesion of the intestinal wall and without strangulation led to mild peritonitis, fusions, and membraniform adhesions. Such pericolic membranes were not different in histology and origin from similar membranes about the uterus and uterine adnexæ, all representing reactions of the peritoneum to irritation.

**The Significance of the Jackson Veil.**—Dr. Daniel N. Eisendrath and Dr. E. W. Schnoor of Chicago stated that from their observations during operations, from dissection of cadavers, and finally from examination of ten fetuses, they believed that certain conclusions could be drawn. The parietocolic fold of Jonnesco synonymous with the pericoloic membrane or Jackson's veil was a reduplication or fold of peritoneum which was constantly found during fetal or post-natal life. That membrane corresponded in every way to the descriptions given by Hale of Jackson's specimens in his two principal papers published in 1908 and 1913 respectively. It was a fine translucent membrane which varied greatly in vascularity. In some of their cases there were only a few fine capillaries, while in others the membrane was extremely vascular. The upper border of that right-sided pericolic membrane was almost invariably at the level of the hepatic flexure and its lower border from 1 to 1½ inches above the lower end of the cecum. Some of their cases the lower border either extended a little farther down and covered the entire cecum and a portion of the appendix or fused with the fold of Treves. In the great majority of these cases this fusion did not occur. The vessels of the pericolic membrane were, as a rule, directed downwards and inwards. In two of their cases the membrane was as thick as ordinary cardboard and showed practically no vessels. In the remainder of the patients the membrane was very thin. It extended inwards across the front of the colon to the attachment of the mesocolon and either fused with the peritoneum, covering the latter, or fused with the omentum along the upper third of the ascending colon. These might be called normal cases. The membrane being a persistence of a fetal structure, under no circumstances should it be stripped off. Such a step would result in leaving an extensive denuded surface. From the examination of specimens and from observations in the living, they believed that the genitomesenteric fold of Reid was the forerunner of the ileopelvic band of Lane and bore the same potential relation to the Lane kink that the pericolic membrane bore to possible kinks of the ascending colon. That such constrictions occurred one could no longer doubt. One case reported afforded ample proof of the rôle which the Jackson veil might ply in the production of acute and chronic obstruction of the ascending colon and cecum. They were not prepared to state at present what caused this change in the pericolic membrane from an innocent persistent fetal structure to the production of a distinct pathological entity. In their opinion Jackson, Pilcher, Gerster, Flint, and others had rendered a great service in calling attention to the various sequelæ of such pathological changes in the pericolic membrane. One of the chief objects of this investigation had been fulfilled by calling attention to the fact that there were two distinct types of pericolic membrane: 1, those which were innocent; 2, those which might cause mechanical interference with the function of the colon. Each case must be judged upon the operative findings and one was not justified in saying that every pericolic membrane required interference. The majority were perfect normal structures. Their examination of fetal cadavers confirmed those of Gray and Anderson, that there was a left parietocolic fold which corresponded in every detail to the same structure on the right side. It was a constant finding in the fetus, and no doubt search for it in the future during operations on the left side of the abdomen would confirm these fetal observations. The treatment of the pathological conditions due to the right pericolic membrane must depend on the findings in the individual case.

**Jackson's Veil or Pericolic Membrane.**—Dr. Arthur N. Collins of Duluth, Minn., said that it was not an easy matter to effect a solution of this riddle. In opening the abdomen he had found a vascular film or veil of greater or less extent in at least 75 or 80 per cent. of cases. How many of these were pathological in the sense that they were giving or would in the future give signs or symptoms? This was a difficult part of the riddle. There were two features upon which the clinical factors of constipation and attendant systemic and local manifestations depended. These were the (1)

extent and (2) thickness of the membranous veil. In his experience, covering some twenty-five or thirty cases, in which the membrane was dealt with, the most frequent location of the veil was upon the ascending colon; next on the cecum; the hepatic flexure alone coming third. Dr. Collins was not prepared to answer the question as to whether the fold of Jonnesco persisted throughout life. Nor was he concerned with the uncertainty of opinion as to whether Jonnesco's fold was one and the same with Jackson's membrane. If an enveloping membrane existed in infancy—and Eastman's studies showed that it did in a certain proportion—it probably persisted into adult life. It was his belief that the membranous veil was intimately concerned in cases of acute or chronic constipation or stasis in the large bowel. By treating the membrane surgically, he had relieved the constipation more often than the pain and tenderness. But there was still an important question which they had to answer: "Was the veil the cause of the constipation, or was the constipation a factor aggravating an already existing veil; or had they to deal with a peculiar type of individual in whom this membranous veil was more prone to occur and become pathologic? Wilms' experience with cecopexy, by which he relieved the pain in all and the constipation in 75 per cent. of his cases, led Dr. Collins to use the method he had diagrammed on the charts. The membrane was tied fast in several places, making stumps and leaving the membranous part of the stump still attached fan-like to the colon. Before closing the wound one or more stumps were anchored to the anterior abdominal wall at points corresponding to the situation of the stump upon the gut.

Dr. L. A. Greensfelder of Chicago stated that in cases in which the abdominal operation was performed, in the quiescent period, where they were enabled to examine the ascending colon, in sixteen instances a Jackson's membrane was found which was not pathological. From his own observation he believed tha the reason sometimes the membrane was not observed in children was because it was a very fine, frail, web-like structure, which, unless one looked for it accurately and carefully, one was very apt to overlook. Through a very small McBurney incision you could without any trouble whatever bring to the surface the ascending colon and a portion of the transverse colon, so that the observation was easily made in children, and he was quite sure that anyone who wished to look for it carefully would find the membrane in every case.

Dr. William S. Bainbridge of New York City followed with remarks on intraabdominal folds and veils.

Dr. Leonard Freeman of Denver said that not long ago he made up his mind to observe in such cases as it was possible to observe the Jackson membrane. Since then he had done thirty-one sections in which the membrane was observed. He found it in twenty-four cases; hence it had been extremely common in his experience.

Dr. Miles F. Porter of Ft. Wayne, Ind., stated that the mere presence of what seemed to be a rather unusual fold in the peritoneal cavity did not necessarily call for an operation of one sort or another upon that fold. In the next place, it did not seem to him that from a practical standpoint it was important to determine whether these folds were of embryonic or pathological origin. It was important to determine as to whether or not they were doing any harm.

Dr. Van Buren Knott of Sioux City, Iowa, said that it had been his experience that more harm resulted from injudicious attempts at handling of bands supposed to be responsible for symptoms than he had seen good results. They should have greater familiarity with this subject before they knew just in what cases they should attempt to liberate or remove the membrane.

Dr. Thomas C. Witherspoon of Butte, Mont., claimed that one error they frequently made was to attribute the whole thing to the bands. Undoubtedly children had these things, but they did not suffer. They were active, they were getting about, there was no stasis, there was no reason for it, and the intensification of the mechanical obstruction by the bands that they got later as they went into their studies or offices, where their habits were sedentary, was due to the occurrence of cesspooling in the bowel and then stasis began.

Dr. Byron B. Davis of Omaha thought that the Jackson membrane was a normal one and was present in a very large percentage of cases; that in most cases when it was normally formed it was really a conservative anatomical structure rather than a pathological one, and he believed that in many instances it served to fix the ascending colon and to prevent a prolapse which would occur in the absence of this membrane.

Dr. A. A. Law of Minneapolis had found this membrane in fifty cases. He said that all of them had been studied with colonic injection of bismuth fluoroscopically and by means of the stereoscope. These studies convinced them that the *x*-ray findings incident to bismuth emulsion were practically of no value except as they showed whether obstruction was present in the large bowel. The large bowel took so many positions according to the posture of the patient that it was of little value. Every individual case of theirs had cecalptosis. The cecum was in the pelvis, or went down there when the membrane was released.

Dr. William T. Reynolds of Kansas City, Mo., had made some observations and investigations of the inside of the abdomen of infants. He had had eleven of these cases, the youngest of which was six months, and the others up to term. In no instance was there an absence of this membrane on the right side of the colon high up, and in no instance was it absent on the terminal ileum. In three cases it was present on the opposite side as observed by Dr. Eisendrath.

Dr. A. A. Kerr of Salt Lake City said that the cases that he had personally seen had been associated with intestinal stasis or chronic appendicitis.

Dr. Clifford U. Collins of Peoria referred to the unanimity with which the reports agreed on certain phases of this question.

Dr. Jabez N. Jackson of Kansas City, Mo., stated that if a person simply found a loose, vascularized veil floating over the colon, that had no bands of fibrous tissue in it definitely interfering with the capacity of the gut somewhere, he should just dismiss it from his mind. When this membrane interfered mechanically with the capacity of the gut it should be divided or stripped off, and this should depend upon the individual case. In some instances a mere slit of an incision was all that was necessary. Sometimes the attachments were so multiple that no simple line of incision would do it, and they had practically to strip the restricting membrane off.

Dr. M. L. Harris of Chicago said that after these membranes were dealt with the patient became a medical case and unless properly treated these membranes would recur, if due to a pathological state in the intestinal wall or to low forms of infection. They could produce experimentally these conditions in animals, and when they found these same conditions existing in the individual, and when they knew the great frequency with which intestinal stasis took place, in his opinion this low infection from intestinal stasis was the underlying factor in this condition.

**Cholecystitis and the Factors That Control Results of Operation.**—Dr. Charles H. Mayo of Rochester, Minn., said that the results of operations for cholecystitis were influenced by many conditions besides those in the gall-bladder itself. Among these, he enumerated infections within the liver and bile ducts which caused changes in the balance of the acidity of the stomach and of the alkalinity of the duodenum, the presence of pyloric spasm and changes in the pancreas. He called especial attention to a group of lymphatic glands extending along the common and hepatic ducts and on the cystic duct. He noted that any case of cholecystitis with sufficient infection to produce symptoms would necessarily affect these glands. In the majority of cases, if these glands were much enlarged, one would find a lymphedema of the head of the pancreas as well as the infection of the gall-bladder. An exception was the general swelling of the mesenteric glands through malignancy or gross abdominal infection. The majority of cases of cholecystitis were undoubtedly best relieved by cholecystectomy.

**Repair of the Common Duct by Means of Transplanted Fascia.**—Drs. Carl B. Davis and Dean D. Lewis of Chicago stated that following partial destruction of the common bile duct, temporary continuity of the passage of bile had been attempted in a variety of ways. In those cases where the remnant of the choledochus could not be implanted into the stomach or duodenum, two methods of repair had been used—the use of a foreign body, such as a rubber tube and various forms of plastic use of the tissues of the body. Sullivan, in 1909, successfully used a rubber drainage tube as a link between the hepatic duct and the lumen of the duodenum. His work was done on dogs. About the same time Wilms and Brewer reported the success of the same procedure in the human. Since that time numerous similar cases had been reported. In most of the reports the tube had passed into the digest-

ive canal and had been expelled. In other cases it had been necessary to reopen the abdomen to remove or readjust the tube. Cahen recently reported a case where the tube did not pass and the autopsy showed an enormous liver abscess. Enderlen had repaired defects in the gall-bladder with omentum. Baldassari and Gardini used flaps of serosa and muscularis for the same purpose. Kehr reported the use of detached flaps from the stomach to repair the choledochus. Kausch and Stubenrauch had constructed tubes, using all the layers of the jejunum and stomach and anastomosing with the permanent biliary fistula already established. The successful use of transplanted fascia in reinforcing the gastrointestinal and urinary tracts led them to believe that fascia might be of use in surgery of the biliary system. In their work they had transplanted free fascia from the abdominal wall to bridge gaps in the common duct and to patch partially severed ducts. In all cases the gastrohepatic omentum was destroyed in so far as any support was given to the choledochus. In one series of cases the common duct was cut across and the ends allowed to retract until they were one-half to one inch apart. A strip of fascia was removed from over the rectus muscle, passed beneath the ends of the severed duct and fastened by silk sutures to the proximal portion of the common duct and passed well up on the cystic and hepatic ducts. The repair at the distal end was done by fixing the fascia to the duodenum behind the entrance of the distal end of the duct into the gut. The fascia was then folded over to form a tube and two continuous sutures used to make the caliber as water-tight as possible; over this the omentum was wrapped as an extra precaution. In the second series of cases the common duct was cut partially across and then slit lengthwise for one-half inch. A strip of abdominal fascia was placed around the duct and the abdomen closed without drainage. In eleven cases it was necessary to close the abdomen without drainage, as the animals pulled out tubes and gauze in the first twenty-four hours. In some cases they tried to divert the bile from the field of repair by draining the gall-bladder, but lost the animals by extravasation of bile into the abdominal cavity after the tubes had been removed by the dogs. Wherever a leak occurred in the region of the flap, the experiment failed. This occurred in three cases—two in the first series and one where the duct was merely slit up. Five dogs were lost from infection of the abduct wall. Three dogs lived two months in the first series. Two of them when killed showed a patent common duct and stools of normal color. The third dog, which lived sixty-five days, had a constriction at the duodenal end. The bile ducts were distended to an enormous degree. The fascia was alive and as resistant as the normal tissues. In one animal where the bile duct had been slit longitudinally, the fascia was sutured too tight at the duodenal end—resulting in marked distention of the gall tracts. In this case the fascia was alive and strong enough to retain the bile.

**The Duodenum—Mobilization, Traumatic Rupture and Toxemia.**—Dr. A. B. KANAVEL of Chicago dealt with three questions; first, the possibility of mobilizing the duodenum; second, a consideration of traumatic rupture, its diagnosis and treatment; third, the question of toxemia developing in those cases in which the duodenum had been ruptured. Attention was called to the difficulty of reaching the third and lower portion of the duodenum by Kocher's method of mobilization and it was suggested to use the following procedure. In the first of the two cases going to operation, the author experienced great difficulty in mobilizing by Kocher's method and in the second case of extraperitoneal rupture of the duodenum he raised the colon and made an incision in the peritoneum between the duodenum and the hepatic flexor of the colon, *i.e.* in the peritoneal covering of the colonic mesentery. The opening was enlarged by the fingers and the entire retroperitoneal duodenum in its lower part was completely exposed, thus allowing of suture and treatment. The second case of extraperitoneal rupture which he reports (both cases were fatal) presented marked toxemia, and death was apparently due to this toxemia rather than to peritonitis, the absence of which was demonstrated by post mortems. The question as to whether the toxemia was due to a secretion of the duodenum or to some other factor was discussed.

**Congenital Pyloric Stenosis.**—Dr. ROLAND HILL of St. Louis, Mo., stated that recent studies of congenital pyloric stenosis had shown it to be a disease of much importance. The frequency of occurrence of this condition was hard to estimate, but it was found to be present in five cases out of one thousand babies studied at the Bethesda Hospital by Dr. T. Wister White of St. Louis, Mo. This estimate of 1-200 seemed to be fairly accurate as to the frequency of the condition. The pathology consisted primarily of great enlargement and thickening of the pylorus caused by hypertrophy of the circular muscle, leading to obstruction of the pyloric opening. In many cases this enlargement could be felt through the abdominal wall as a small movable tumor. The symptoms of the disease usually manifested themselves between the third and sixth week of life. The earliest symptom was vomiting, which was usually projectile in character; it was often so marked that little or no food was retained. Appearing at the same time were the gastric waves so characteristic of the affection. Constipation was very marked, sometimes absolute, and a tumor might be felt. The treatment might be either medical or surgical. If obstruction was marked, surgery alone afforded a chance of relief. The operation best adapted to these cases was posterior gastroenterostomy. Dr. Hill had operated upon ten of these cases, five of which had recovered and five had died. One of these five deaths was due to a kink and the other four to complications existing at the time of operation. He reported a successful operation upon a premature child five weeks old that weighed only 3 pounds and 15 ounces. This child gained 3 ounces in the first two weeks, 4½ ounces in the third week, 12½ ounces in the fourth week, 1 pound the sixth week, and still continued to gain at the rate of about 2 ounces a day. This was apparently the smallest child upon record to recover after operation for this disease.

*(To be concluded.)*

---

### PHILADELPHIA NEUROLOGICAL SOCIETY.

AT a stated meeting held December 22 Dr. WILLIAMS B. CADWALADER presented a communication entitled "A Case with Bilateral Paralysis of the Muscles of Deglutition and Anesthesia Limited to the Left Upper Extremity, Left Shoulder and the Distribution of the Second Branch of the Left Fifth Nerve." The patient was a syphilitic and the symptoms had been present, after a sudden onset, in varying intensity for a period of six years. There had at one time been diplopia, but the eyegrounds presented no lesion. The condition was thought to be dependent upon thrombosis of the right posterior inferior cerebellar artery.

Dr. GEORGE WILSON exhibited a patient presenting "Tetanoid Chorea, with Anarthria and Exaggerated Reflexes, but No Babinski Response, Probably Due to Lenticular Disease." The man had had an attack of hemiplegia, shortly followed by a second attack of paralysis involving the opposite side. Apparently he understood what was said to him, but he was unable to make intelligible reply, succeeding at times, however, in making some sound. Any attempt at voluntary movement was followed by more or less violent jactitation of the musculature concerned. There was marked difficulty in deglutition, the act being accomplished only with considerable effort.

Dr. WILLIAM G. SPILLER exhibited a specimen of "Extensive Bilateral Subdural Hemorrhage Over the Motor Cortex, Without Motor Paralysis or Irritation." The patient had been struck on the head by a bag of paper weighing, it was thought, about 150 pounds, and falling from a height estimated at 14 feet. The man said he felt as if his neck had been broken, but he did not lose consciousness. He complained of headache, but at no time did he present any motor disturbance, nor did he have any convulsions. The optic discs were blurred. Without apparent further cause the patient became stuporous, then comatose, and finally death took place. Post-mortem examination disclosed extensive hemorrhage beneath the dura over both cerebral hemispheres, without sign of fracture of any bone of the skull.

Drs. SEYMOUR D. W. LUDLUM and ELLEN P. CORSON-WHITE presented a communication entitled "Tests for Latent and Treated Cases of Syphilis." They pointed out that in a not inconsiderable number of cases of syphilis negative responses to both Wassermann and Noguchi tests are obtained, while a positive response is secured with the luetin test. Accordingly no case should be considered as conclusively non-syphilitic in which the luetin test has not been shown to be repeatedly negative.

Drs. ARTHUR GERHARD and HENRY K. DILLARD reported "A Case of Syphilis Presenting Unilateral In-

volvement of Certain Cranial Nerves." The patient was a negro, 23 years old, with a clear history of luetic infection and with a positive Wassermann reaction. He had a typical right-sided facial palsy, with anesthesia of the cheek, deviation of the tongue to one side, loss of taste and paralysis of the soft palate.

## State Medical Licensing Boards.

### STATE BOARD EXAMINATION QUESTIONS.

LOUISIANA STATE BOARD OF MEDICAL EXAMINERS.

*October* 27, 28, and 29, 1913.

(*Continued from page* 368.)

PATHOLOGY.

1. (*a*) What is an infarct? (*b*) What is an anemic infarct? (*c*) What is a hemorrhagic infarct?
2. Describe the process of healing of wounds by first intention.
3. Name the different forms of pus-producing cocci, and state which of these are the most virulent.
4. (*a*) What is suppuration? (*b*) What is leucocytosis?
5. What changes occur in joints following gonorrheal metastasis?
6. Describe the pathology of acute osteomyelitis.
7. What are the pathological changes found in the small intestine in typhoid fever?
8. Describe the gross pathology of acute lobar pneumonia.
9. Describe the pathology of pyonephrosis.
10. Describe the pathology of arteriosclerosis.

THERAPEUTICS.

1. (*a*) What are mydriatics? (*b*) Name them.
2. Name the principal drugs used for the reduction of blood pressure.
3. (*a*) What are cardiac stimulants? (*b*) Name some of the best known drugs used for this purpose.
4. Describe the physiologic action of the diuretics.
5. How would you treat a case of acute opium poisoning?
6. What are the antidoes for arsenic?
7. Describe the treatment of valvular disease of the heart with failing compensation.
8. How do substances act by counterirritation? Name some of the best known counterirritants.
9. Describe the action of antidiphtheritic serum in a case of diphtheria.
10. What are the physiological actions of the salts of cinchona?

OBSTETRICS.

1. (*a*) What are the causes of prolonged first stage of labor? (*b*) dangers? (*c*) management?
2. Discuss in general the principal drugs used to hasten labor.
3. What are the prerequisites, indications and contraindications for the use of forceps?
4. What are the causes of hemorrhage before and after delivery?
5. (*a*) What conditions necessitate version? (*b*) forceps delivery? (*c*) cesarean section?
6. Describe a cesarean section.
7. Vaginal examination shows the saggital suture occupying the right oblique diameter; the small fontanelle is felt opposite the right sacroiliac synchrondrosis, the large fontanelle being directed toward the left and front. (*a*) What is the position of the child? (*b*) how may the case end? (*c*) treat the case if nature's efforts are unsuccessful.
8. What changes occur in the fetal circulation at birth?
9. Give the etiology and treatment of subinvolution of the uterus.
10. What is the cause and treatment of frequent urination in pregnant women?

### ANSWERS.

PATHOLOGY.

1. An *infarct* is an area of degeneration and inflammation caused by the plugging of an end artery. An *anemic infarct* is one in which there is no blood. In a *hemorrhagic infarct* there is blood.

2. *Healing of wounds by first intention.*—"Exudation of plasma from the neighboring blood-vessels occurs, and its fibrinogen is converted into fibrin, so gluing the edges of the wound together. Leucocytes are poured out and infiltrate the wound, absorbing any blood clot present. These are followed by fibroblasts (connective-tissue cells), which take their place. New capillaries form by budding out from adjacent ones, and vascularize the new tissue. Fibrous tissue is formed by intercellular exudation from the fibroblasts and so the fibrocicatrical union is complete, for at the same time epithelium is spreading over the narrow surface line."—(*Aids to Surgery*).

3. The *pus-producing cocci* are: *Staphylococcus pyogencs aureus, Staphylococcus pyogcnes albus, Staphylococcus pyogenes citreus, Streptococcus pyogenes, Staphylococcus cereus, Micrococcus tetragenus,* gonococcus. The *Streptococcus pyogenes* is the most virulent.

4. *Suppuration* is a condition in which pus is present, and there has been some destruction of tissue following inflammation. *Leucocytosis* is a condition in which the white blood-corpuscles are increased in number.

5. *Gonorrheal arthritis.*—"One or several joints may be involved, generally the former, the knee, ankle, and wrist being most frequently affected. The inflammation may be acute or chronic, and varies in extent as well as in degree. Although the synovial membrane alone may be involved, the ligaments and periarticular structures are very apt to be thickened and infiltrated. Except in the mildest cases, the pain is severe and there is fever. Suppuration may occur, and ankylosis is very prone to follow even the milder cases."—(Stewart's *Surgery.*)

6. *Acute osteomyelitis:* "The marrow first becomes red and edematous, then cellular infiltration and proliferation are superadded, and finally collections of pus or diffuse purulent transformation follow. The surrounding bone is involved, becoming more or less infiltrated, softening, and not rarely undergoing necrosis. Small or large sequestra may be formed, or the bone may necrose completely. Periostitis is generally associated, and the tissues around the bone are usually infiltrated and suffer suppurative or necrotic changes. Hypertrophic changes may occur in the periosteum and superficial layers of bone, causing a bony encasement of central sequestra. In such instances a suppurating sinus, extending from the bone to the surface, usually remains."—(Stengel's *Pathology.*)

7. "Principally inflammation of the lymphoid tissue of the lower portion of the ileum, with more or less catarrh throughout the bowels. Peyer's Patches—1st week.—Are swollen through infiltration of leucocytes, the surface raised and fawn-colored—the infiltration involves the submucous coat. The lesions are most numerous at the lower end of the ileum. 2nd week.—The surface becomes abraded; sloughs form, which are often bile-stained. 3rd week.—Sloughs come away, leaving ulcerating surfaces. Typical typhoid ulcers are thus formed. A few solitary glands undergo the same process. At the end of the week the ulcers begin to granulate, but healing is usually slow. Mesenteric glands may undergo the same changes, but more often become swollen, red, and tender only, or break down into cheesy masses."—(Wheeler and Jack.)

8. *Lobar Pneumonia.* "(1) *Stage of engorgement.*—This is the stage of inflammatory hyperemia and edema, and it is characterized microscopically by overfullness and slight tortuosity of the pulmonary capillaries, and by swelling of the alveolar epithelium. The lung is of a dark red color; it is heavier and less crepitant than natural: it pits on pressure; and its cut surface yields a reddish, frothy, tenacious liquid.

"(2) *Red hepatization.*—Here there is an exudation of liquor sanguinis and blood corpuscles. The exuded liquids coagulate within the alveoli and terminal bronchioles, the coagulum enclosing numerous white and a few red blood corpuscles. The alveolar epithelium is swollen and granular. The lung is now much heavier than in the preceding stage, and is increased in size, so as to be often marked by the ribs. It is quite solid; sinks in water, and cannot be artificially inflated. It is remarkably friable, breaking down with a soft granular fracture. The cut surface has a markedly granular appearance, seen especially when the tissue is torn, and due to the plugs of coagulated exudation-matter which fill the alveoli. The color is of a dark reddish-brown, often here and there passing into gray. This admixture with gray sometimes gives a marbled appearance. The pleura covering the solid lung always participates more or less in the inflammatory process. It is opaque, hyperemic, and coated with lymph.

"(3) *Gray hepatization.*—This stage is characterized by a continuance of the process of inflammatory cell-emigration, and by more marked changes in the epithelium. The white blood corpuscles continue to escape from the vessels, and the alveolar epithelium becomes more swollen and granular. The alveoli thus become more completely filled with young cell-forms, so that the fibrinous exudation is no longer visible as an independent material. The fibrinous exudation now disintegrates, and the young cells rapidly undergo fatty metamorphosis. The alveolar walls themselves, with few exceptions, remain throughout the process unaltered, although very occasionally, when this stage is unusually advanced, they may be found here and there partially destroyed. Owing to these changes, the reddish-brown color of the lung becomes altered to a grayish or yellowish white. The granular appearance is much less marked; the solid tissue is much softer and more pulpy in consistence, and a puriform liquid exudes from the cut surface of the organ. This stage, when advanced, has been termed 'suppuration or purulent infiltration' of the lung."—(Quain's *Dictionary of Medicine*).

9. *Pyonephrosis* is that form of suppuration in the kidney and its pelvis which is associated with obstruction to the outflow of urine. "The infection is commonly an ascending one, being formed by the increased backward pressure. As a result of chronic inflammation, the walls of the ureter become thickened and fused with the peritoneum and surrounding tissues, and the lumen is usually dilated. On section the kidney presents a number of abscess cavities, the intervening parenchyma being pale and tough as a result of chronic interstitial nephritis. Unless there has been antecedent hydronephrosis, the pelvis is usually small in proportion to the greatly enlarged and flask-shaped calyces, which constitute the abscess cavities and form the chief bulk of the kidney. Their communications with the pelvis and with each other are narrowed or obliterated, so that they may be regarded as separate cavities. The purulent contents are often mixed with crumbly masses of phosphates. The mucous membrane of the pelvis and calyces is converted into granulation tissue, and, in advanced cases, becomes the seat of ulceration which eats into the parenchyma. The renal blood-vessels are thickened and narrowed by endarteritis, so that there may be very little hemorrhage when the pedicle is divided. The perinephric cellular tissue is converted into granulation and scar tissue, and is frequently the seat of scattered foci of suppuration, and sometimes a large perinephric abscess is found to communicate directly with one of the dilated calyces. The perinephric suppuration may extend into the psoas and quadratus muscles, or into the cellular planes of the abdominal wall."—(Thomson and Miles' *Manual of Surgery.*)

10. *Arteriosclerosis.*—The large arteries are chiefly affected. The earliest changes are a small-celled infiltration of the subendothelial tissue, which may be either replaced by fibroid tissue or undergo fatty degeneration. Degeneration usually occurs, and the softened mass either bursts into the artery or becomes converted into a calcareous plate. The process extends to the middle coat, which is at first softened, and the muscular tissue is destroyed in patches. The result is either weakening of the wall and dilatation into an aneurysm, or the deposit of lime salts and calcification of the middle coat. The external coat is thickened, and helps to prevent dilatation. The conditions which are secondary to atheroma are thrombosis, detachment of a plate forming an embolus, or "dissecting aneurysm," due to the blood-stream getting under a plate and tunneling under the tunica intima.

THERAPEUTICS.

1. *Mydriatics* are agents which cause the pupil of the eye to dilate. The chief are:—Atropine, homatropine, daturine, coniine, hyoscyamine.

2. *The principal drugs used for the reduction of blood-pressure:*—Amyl nitrite, sodium nitrite, potassium nitrite, nitroglycerin, erythrol tetranitrate, veratrum viride, aconite.

3. *Cardiac stimulants* are agents which promptly increase the force and frequency of the heart when it is depressed. The chief are:—Alchohol, ammonia, nitroglycerin, heat, ether, camphor, sparteine.

4. PHYSIOLOGICAL ACTION OF DIURETICS. *"The refrigerant Diuretics* modify rather than increase the urine, and exercise a sedative action upon the heart and circulation. Used to excess they depress the heart and impoverish the blood. *Hydragogue Diuretics* increase the water of the urine largely, and in general act by raising arterial pressure, either—(*a*) throughout the body, or (*b*) locally in the kidneys. This they accomplish in various ways, direct and indirect—increasing the action of the heart, contracting the efferent vessels so as to raise the pressure in the glomeruli, dilating the afferent vessels, etc. The *Stimulant Diuretics* are largely eliminated by the kidneys, and act upon the entire genitourinary mucous membrane by local irritation, which in excess causes inflammation and symptoms of a violent character, as strangury, bloody urine, etc. All the members of this group should be used with great caution."—(Potter's *Materia Medica.*)

5. In a case of *acute opium poisoning*, an emetic should be given, the patient's stomach should be washed out, a one per cent. solution of potassium permanganate may be used to wash out the stomach, the circulation and respiration must be maintained, the patient should not be allowed to rest, strong coffee or caffeine may be administered by the mouth or rectum, the urine should be drawn by a catheter.

6. The *antidote for arsenic* is freshly prepared solution of ferric hydroxide; a hypodermic of apomorphine should be given.

7. "Where compensation has failed, cardiac tonics are required, and of these digitalis stands first. It acts beneficially by slowing the action of the heart and prolonging its diastole, thus increasing the natural rest. It also increases the force of the cardiac beat. In addition, it has a diuretic action and thus tends to relieve dropsy. Its disadvantages are that it increases resistance in the peripheral arteries and so produces greater strain, and that in aortic regurgitation the prolonged diastole permits of a longer back-flow. Consequently it should not be given in aortic regurgitation unless there are mitral symptoms. . . . Sudden breakdowns of compensation call for complete rest and stimulation of the heart by ammonia or ammonium carbonate. Where the right heart is overdistended strychnine hypodermically, along with a mercurial purge, and, if necessary, removal of blood by leeches over the liver or by bleeding from the arm are required."—(Wheeler and Jack's *Handbook of Medicine.*)

8. "The entire basis for the employment of counter-irritation rests upon reflex action, or the conduction of a nerve impulse to a center, which, when so stimulated, sends out an impulse to the part of the body which is diseased."—(Hare's *Therapeutics.*)

*Counterirritants:* Mustard, iodine, capsicum, chloroform, camphor, ammonia, cantharides, croton oil, hot water.

9. *How* antitoxin produces immunity and effects cure is not known, but *theories* deduced from observed facts are as follows: "As the various pathogenic bacteria produce the causative toxins of their respective diseases, so the organic cells of the body, reacting under the stimulus of the poisons thus introduced, immediately proceed to elaborate defensive bodies, which if produced in sufficient quantity will neutralize the effects of the toxins. Residual antibodies remaining in the blood after recovery render the animal immune for a time against the disease. The immunizing and curative effects obtained by the injection of the blood serum of an immunized animal into the circulation of another animal are due either to direct chemical neutralization of the toxins themselves by the antibodies so introduced (Behring, Kitsato), or to a particular influence exerted by the antibodies upon the living cells of the organism which, being affected in two opposite directions, remain neutral to the disease (Buchner). Some authorities hold that these results are due to the conjoint action of leucytic and chemical forces. Ehrlich's side-chain theory assumes that every toxin contains toxophore molecules having direct toxic action, and hantophore molecules which combine the toxophores with a similar combining group of molecules in the tissue cell of the attached organism. The tissue cell molecules being destroyed by the toxophores, a rapid and profuse regeneration of similar molecules occurs in side chains, and these molecules overgrowing are carried into the circulation, becoming the antitoxin, which acts by combining with the haptophores of newly arrived toxin, using up their combining power before they can reach the tissue cells."—(Potter's *Materia Medica*, etc.)

10. *Physiological action of the salts of cinchona:* They are antiseptics, bitter tonics, and antipyretics; at

first they improve appetite and aid digestion; later they cause gastric catarrh; in small doses they act as a cardiac tonic; later they slow the heart's action; small doses stimulate the brain, large ones cause ringing in the ears, disturbances of vision, delirium, dilated pupils, a sense of fullness in the head; the spinal cord is first stimulated, then depressed; and the urinary secretion is increased by these salts.

OBSTETRICS.

1. PROLONGED FIRST STAGE OF LABOR. *Causes:* Obstruction, uterine inertia, uterine exhaustion. *Dangers:* Asphyxiation of fetus, postpartum hemorrhage, sepsis, pressure-necrosis and fistulæ, exhaustion or death of the mother. *Management:* The case should be treated early; causes should be removed when possible; a warm vaginal douche, and the administration of morphine, chloral, or quinine have been recommended; delivery by forceps may be necessary.

Uterine inertia is *primary*, when it is simply characterized by weak pains from the beginning. In *secondary* inertia the labor has begun in a normal way, but pains have given out, and there is a condition of uterine exhaustion. Primary inertia requires rest, strychnine, and (some say) ergot; secondary inertia needs sleep, chloral, bromides, and opium. In the primary form version or artificial delivery may be indicated.

2. "Oxytocics are drugs that tend to accelerate parturition by increasing the expulsive force of the uterus. It is conceivable that they may act directly by stimulating the unstriped muscle of the uterus, or indirectly by influencing a center for uterine contraction supposed to exist in the lumbar spinal cord. The chief oxytocics are ergot, quinine, hydrastis, cotton-root bark, and corn smut. Oxytocics may be employed during labor to hasten the expulsion of the fetus; at the close of labor, to prevent or to check postpartum hemorrhage; and in the puerperium to overcome certain forms of subinvolution.

"In the parturient woman small doses of *ergot* induce uterine contractions which often closely resemble the rhythmic contractions observed in normal labor. After full doses, however, the contractions usually become very powerful, and uninterrupted or tetanic. The preparations of the drug on the market vary so much in activity that it is quite difficult to predict the effect of an average dose in a given case.

"*Quinine* has some power of increasing the rapidity and energy of the uterine contractions when they have once begun; its action, however, is inconstant. The contractions are much less prolonged than those excited by ergot and are probably due to an influence exerted directly on the uterine muscle."—(Stevens' *Modern Materia Medica.*)

3. *Prerequisites for the use of forceps* are: (1) The rectum and bladder must be empty; (2) the os uteri must be fully dilated; (3) the membranes must be ruptured; (4) the pelvis must be of sufficient size.

*Indications for the use of forceps* are: (1) *Forces at fault:* Inertia uteri in the presence of conditions likely to jeopardize the interests of mother or child. (*a*) Impending exhaustion; (*b*) arrest of head, from feeble pains. (2) *Passages at fault:* Moderate narrowing, 3¼ to 3¾ inches, true conjugate; moderate obstruction in the soft parts. (3) *Passenger at fault:* A. Dystocia due to (*a*) occipitoposterior, (*b*) mentoanterior face. (*c*) breech arrested in cavity. B. Evidence of fetal exhaustion (pulse above 160 or below 100 per minute). (4) *Accidental complications:* Hemorrhage; prolapsed funis; eclampsia. All acute or chronic diseases or complications in which immediate delivery is required in the interest of mother or child, or both. *Contraindications:* Mechanical obstruction in the parturient canal; incomplete dilatation of the os; non-rupture of membranes; non-engagement of the presenting part; the fetal head being too large or too small; distended bladder or rectum.

4. The following (from Gould and Pyle's *Cyclopedia of Medicine and Surgery*) is a useful classification of the hemorrhages in question:

*A. Hemorrhages of Pregnancy:* Caused by (1) placenta prævia; (2) premature separation of a normally situated placenta; (3) apoplexy of the decidua or placenta.

*B. Hemorrhages of Labor:* Caused by (1) placenta prævia; (2) premature separation of a normally situated placenta; (3) relaxation of the uterus; (4) laceration of cervix; (5) rupture or inversion of uterus.

*C. Hemorrhages of the Puerperium:* Caused by (1) retained secundines; (2) displaced uterus; (3) displaced thrombi; (4) fibroid tumors; (5) hypertrophied decidua; (6) carcinoma.

5. (*a*) *The Indications for Version are:* (1) In transverse presentations; (2) in placenta prævia; (3) in malpresentations of the head; (4) in simple flattened pelvis, and in minor degrees of pelvic contraction; (5) in prolapsed funis; (6) in sudden death of the mother; and (7) in any case where speedy delivery is imperative.

(*b*) See QUESTION 3.

(*c*) *Cesarean section* (conservative). "*Indications:* The cases in which it is performed are: (1) Extreme deformity of the pelvis, in which delivery by forceps and version is excluded, and in which craniotomy is either impossible or would be more dangerous to the mother than cutting into the abdomen and uterus; and in which there is not room for a successful symphyseotomy. Such cases present the '*positive*' indication for cesarean section; there is nothing else to be done. Flat pelves having a conjugata vera of 2¼ inches or less, and justo-minor pelves with a conjugata vera of 2½ inches or less, present this positive indication; (2) cases of more moderate pelvic contraction in which craniotomy is possible, but cesarean section is agreed upon to *save the life of the child;* (3) mechanical obstruction in the pelvis from fibroid, cancerous, bony, or other tumors which cannot be pushed up out of the way or be safely removed; (4) irreducible impaction of a *living* child in transverse presentations; (5) in women dying near the end of pregnancy the child, if alive, is rapidly delivered by *post-mortem* cesarean section; (6) various other obstructions from inflammatory adhesions, atresia, constrictions, etc., of the vagina, and uterine displacements, may rarely require the operation; (7) recently the operation has been done in eclampsia cases, where more conservative methods of rapid delivery were impracticable; and (8) in placenta prævia, chiefly with a view to lessen the infant mortality attending the usual treatment of this complication."—(King's *Obstetrics.*)

6. *Cesarean section:* "Fluid extract of ergot, ℥xx, is injected into the thigh muscles just as the anesthesia is begun. The operator assures himself that there is no loop of intestine between the uterus and abdominal wall, beneath the field of incision. Should a coil of intestine be found there, it is pushed above the fundus. An assistant holds the uterus in central position. The skin incision extends one-third above and two-thirds below the level of the umbilicus. It is best made through the right rectus muscle. The external layer of the rectus sheath is divided, the muscular bundles separated with handle of scalpel and the fingers, and the deep layer of the sheath and the peritoneum divided after lifting them with tissue forceps. Bleeding vessels are controlled by gauze sponge, pressure, or held by catch-forceps before opening the peritoneum. A short longitudinal median incision is made in the uterine wall beginning at the fundus, avoiding the membranes if still unbroken. This is extended downward with fingers, scissors, or scalpel to a total length of about six inches. The hand is thrust through the membranes and the child is extracted by the head or the feet, whichever is most accessible. In case of anterior implantation of the placenta, usually the hand may best be passed directly through it. The cord is clamped at two points with catch-forceps, cut between them, and the child is passed to an assistant. The uterus slips out of the abdomen as the child is extracted, and the intestines are kept back with hot sterilized towels placed over the upper part of the incision. The coverings help also to protect the peritoneum from soiling. The uterus is wrapped in hot moist cloths. As a rule, it is better not to wholly eventrate the uterus. The placenta, if not spontaneously separated, may be peeled off by grasping it with one hand like a sponge. If the cervix is not sufficiently open for drainage, a large rubber tube or gauze strip is passed down through it and withdrawn from below. Irrigating or mopping the uterine cavity is unnecessary. Asepsis is promoted by leaving it as nearly as possible untouched. The peritoneum is sponged dry with the least possible friction or handling. The uterine wound is closed with deep No. 2 chromated catgut sutures at intervals of about 1/3 inch. They are given a wide sweep laterally through the muscular wall, falling short of the decidua. The peritoneal coat of the uterus is closed with a No. 1 continuous plain catgut suture, forming a welt over the deep suture line. The hemor-

rhage is inconsiderable and usually ceases with the introduction of the first sutures—a hypodermic of ergot should be given before beginning the operation, and one of ergotole and pituitrin on the delivery of the child. Retraction of the uterus is ensured by manipulating it, if necessary, through a hot towel, or by faradism. When there has been much blood lost, a quart or two of warm sterilized 0.9 per cent. salt solution may be left in the peritoneum. The parietal peritoneum is closed with a plain running No. 0 catgut suture. Interrupted silkworm-gut sutures are then passed at intervals of about¾ inch, through all but the peritoneum, from within outward. The fascia is brought together with interrupted No. 2 plain catgut sutures, or with a continuous suture. The silkworm-gut sutures are now tied. The abdomen is cleansed, and the wound covered with a dressing of several thicknesses of dry sterile cheesecloth; over this is placed a thick compress of sterile absorbent cotton. The dressings are secured by means of strips of zinc oxide adhesive plaster, and are held in place by a Scultetus binder." (Polak's *Obstetrics.*)

7. (*a*) The position is right occipitoposterior.

(*b*) The *case may end* by rotating to an anterior position, or by becoming a permanent posterior position, or by becoming a face presentation.

(*c*) *Management*—"(*a*) *When diagnosed while the head is at the brim.* (1) Leave it alone. The occiput will probably rotate to the front all right if it is given plenty of time. (2) If flexion appears to be deficient, try to increase it by pushing up the sinciput with the fingers in the vagina during a pain, at the same time pressing down upon the fundus with the other hand. (3) The head may be rotated by passing the hand into the vagina and grasping it between the fingers and thumb. At the same time the shoulders must be rotated by abdominal palpation, or else the head will at once go back to its original position. This maneuver generally requires an anesthetic.

"(*b*) *When diagnosed after the head has entered the pelvis.* (1) Leave it alone. After exercising the patience of all concerned, it will probably rotate spontaneously. Only about one case out of twenty fails to do so. (2) An attempt may be made to increase flexion as before. (3) Manual rotation may be attempted as before, but the head must first be flexed and gently pushed back out of the pelvis. (4) If the pains are weak, forceps should be applied well back on the head, so that when traction is applied flexion will be promoted. The head should then be pulled well down on to the pelvic floor. If it begins to rotate, take off the forceps and leave the rotation to nature, merely keeping the head on the pelvic floor by pressure on the fundus. After the rotation has taken place the forceps may, if necessary, be reapplied and delivery completed thereby.

"(*c*) When the occiput has definitely rotated into the hollow of the sacrum, and the case has become a persistent occipitoposterior, forceps should be applied and the head delivered with the occiput posterior. The perineum should be guarded as much as possible, and any tears stitched up at once. In extreme cases craniotomy and pubiotomy may require to be considered."—(Johnstone's *Textbook of Midwifery.*)

8. *Changes that occur in the fetal circulation at birth:* The hypogastric arteries dwindle and close, the foramen ovale becomes obliterated, the ductus arteriosus and ductus venosus become obliterated, the umbilical vein becomes impervious, and the Eustachian valve atrophies.

9. SUBINVOLUTION. *Etiology:* Laceration of the cervix; absorption of septic products; mismanagement of the convalescent stage of the puerperium, chiefly too early rising; tedious labors; misplacement of the uterus; retained clots or membranes; tumors of the uterus. *Treatment:* Rest in bed, hot intrauterine and vaginal douches, correction of constipation, abstention from sexual intercourse, tonics, correction of displacement, and, if necessary, curettage. An abdominal binder may be worn.

10. Frequent urination in pregnancy is due (1) to uterine displacement, chiefly anteflexion, occurring at the beginning of pregnancy; (2) to pressure of the presenting part on the bladder, occurring toward the end of pregnancy. A displaced uterus may be replaced; the patient should drink as little fluid as possible; tincture of hyoscyamus has been used by some practitioners with benefit.

## Miscellany.

**Medicine and Divinity.**—A writer in the *British Medical Journal,* October 4, 1913, narrates the history of Sir Francis Milman, who was admitted a Fellow of the Royal College of Physicians in 1778; but apparently just about that time he was nearly lost to medicine and gained by the Church, for he took the degree of bachelor of divinity at Oxford on November 10 of that year, and soon thereafter resigned his appointment as physician to the Middlesex Hospital. The intention, however, was abandoned, and he is found to be, in 1785, physician extraordinary to the King's household; and then, having, so to say, put his foot on the ladder, he is seen mounting steadily—physician to the household, physician extraordinary to the King, physician in ordinary to the Queen, and, in 1806, physician in ordinary to the King. He was created a baronet in 1800. If Sir Francis at any time regretted that he did not leave medicine for divinity he must have been consoled to some extent by the fact that he lived to see his third son (Henry Hart Milman) take orders (1816); in that year also a grandson was born (Robert Milman), who was in time to come (1867) to be bishop of Calcutta. Henry Hart Milman also rose high in the Church, being made dean of St. Paul's by Lord John Russell in 1849; he was known as "the great dean," and is now remembered for many of his literary undertakings.

**Prevention of Loss of Life at Sea.**—At the recent International Congress on First Aid and Ambulance Work, held in Vienna, the prevention of loss of life in sea voyages was discussed in a paper by Professor Flamm, who said that watertight compartments should be constructed in the long axis as well as in the cross-section of a modern ship, the stability of the vessel being of paramount importance. The number and capacity of the life-boats should be in direct relation to the number of persons on board the ship, and not to the tonnage of the vessel. A modern passenger steamer must have apparatus for wireless telegraphy, must be carefully ballasted by proper storing of the cargo and trimming of the fuel, and must have the fuel stored in fireproof compartments. Medical aid must be provided for each 300 or 500 souls, one medical man and a ship's hospital or ward, with at least six beds, being available. Cork belts must be within easy reach in the berths and on deck.—*Lancet,* October 4, 1913.

**Economy of Fuel.**—It is not the amount of gasoline that determines the amount of power to be derived from a given cylinder. It is the amount that can be changed into vapor and mixed with air to a proper degree before ignition. In winter much gasoline is wasted by being carried as liquid into the cylinders. Such material burns very slowly as compared with the proper mixture, and leaves much of the carbon deposited in the combustion chambers. This is not economy.—*Motor.*

**Life of Dry Cells.**—When dry cells are used for starting purposes, a season's use may be considered their average life. If a set of cells in this service deteriorates rapidly, the obvious assumption is that there is a short circuit somewhere down the line or the driver has forgotten to turn the switch after the engine starts. A small, two-point switch, placed "under the driver's nose" generally serves to refresh the memory of even the most careless.—*Motor.*

### THE EXTENSION OF TUBERCULOSIS IN THE IMMUNE LUNG.

By DR. GEORGE E. BUSHNELL,

U. S. ARMY.

FORT BAYARD, N. M.

We learn from animal experimentation that while large inoculations with tubercle bacilli produce an acute, disseminated, rapidly fatal tuberculosis, it is possible by the administration of a small enough dose to produce a type of chronic localized tuberculosis which much resembles the chronic pulmonary tuberculosis of man. Furthermore, animals which have a tuberculosis of a chronic type have been shown by properly conducted experiments to be immune to reinfection from without, and the fact of localization of the tuberculosis and its slow course in such animals seems to point to the existence of at least a partial immunization as respects the spread of the already established disease. Many facts point to an analogous immunity in man. The purpose of this article is to endeavor to explain and coordinate certain facts as to the extension of the chronic tuberculous process within the human lung on the assumption that a relatively small infection with tubercle bacilli confers a more or less perfect immunity toward tuberculosis and that the typical localized and slowly progressive pulmonary tuberculosis of the adult owes its peculiarities to the existence of such immunity.

Tubercle bacilli enter the human body for the most part by deglutition and inhalation. Bacilli which infect the cervical and mesenteric glands pass through an apparently unchanged mucous membrane. V. Baumgarten, it is true, finds microscopic evidence that damage is inflicted upon lymphoid tissue by the bacilli during their penetration, but the fact remains that the development of manifest tubercle at the point of entry is exceedingly rare. As for the lungs there are many obstacles to purely aerogenous infection of the pulmonary parenchyma. The vast majority of tubercle bacilli which enter the air passages must be deposited upon the mucous membrane as Saenger[1] has shown. In this case if they enter the tissues they do so after penetration of the mucous membrane of trachea or bronchi.

It is held by many that tubercle bacilli reach the alveoli directly by the inspired air. But if this does occur, evidently the bacilli cannot be agglomerated into clumps. In order to penetrate so deeply they must be suspended in impalpable dust or be contained in finely atomized fluid, which practically necessitates the breaking up of aggregations into their individual bacilli. According to Kretz[2] tubercle bacilli after reaching the alveoli under the conditions of animal experiment, quickly disappear therefrom, that is they enter the lymph vessels, and if not clumped are probably transported to lymph glands as in infections elsewhere. We may say, therefore, that, as a rule, the tubercle bacilli of primary infections enter lymph channels one by one and are transported to lymph glands.

Bartel[3] has shown that tubercle bacilli undergo a diminution in virulence in passing through a mucous membrane and that their virulence is still further diminished after they have reached the lymph glands, so much so that for a time they may become completely avirulent. It has been found by inoculations of the gland substance of both man and animals that the bacilli may be present without producing visible changes in the tissues and that they may remain latent even to tuberculin tests for weeks at least, that is, they do not necessarily at once produce systemic infection. From the fact that tubercle is not formed at the point of entry of the single bacillus and from the additional fact of the latency of tubercle bacilli in lymph glands it may be concluded that the single bacillus does not produce a systemic reaction, that is, does not infect the organism. If this is true of the single bacillus it is equally true of disseminated and isolated bacilli. Tubercle bacilli do not infect until they have multiplied or have otherwise become aggregated. In other words, there is a threshold of infection below which tubercle bacilli are unable to arouse sufficiently the resistance of the body to produce the necessary reaction to their presence. The need of aggregations of tubercle bacilli in order to produce infection would seem to show that somewhat of a concentration of their toxic products may be requisite as well as a concentration of the bacilli themselves. The individual bacillus is a more or less inert substance. It is only when the bacilli are massed together that their toxic products become a sensible irritant to unsensitized cells. What number of bacilli thus aggregated is necessary in order to reach the threshold of infection is not known. It probably varies with the individual and with the virulence of the strain of bacilli. The figures given by authors as to the number of tubercle bacilli necessary for infection are not significant, for multiplication after introduction is not excluded.

If it is true that the single bacillus cannot cause the primary infection it is still more true that after the primary infection has produced an immunity, and so long as that immunity exists, isolated bacilli, whether few or numerous, and whether derived from without or from the primary focus, cannot cause secondary lesions.

This proposition would be disputed by those who believe that the sensitization of the organism to tuberculous infection renders it more rather than less subject to extensions of the tuberculous process. Undoubtedly immunization is slow in reaching its full development and large doses of tubercle

bacilli, artificially introduced, may result in superinfections while the immunity is still imperfect. These are, however, rather to be counted as a part of the primary infection.

What happens to small collections of tubercle bacilli in the human body when immunity has fairly developed may be shown by a brief consideration of the subject of what may be called the primary multiple infection, or more properly speaking, the multiplicity of collections of tubercle bacilli before or at the beginning of the first systemic reaction to the tubercle bacillus. It is probable not only that tubercle bacilli are collected in more than one gland during the process of primary infection, but also that all tubercle bacilli do not enter the body by the same portal in the given case. The choice of the portal of entry is doubtless much influenced by the mode of administration of the tubercle bacilli. Thus Bartels[3] found that infections of the mesenteric glands much preponderated when young rabbits were given a single feeding with food containing human tubercle. But if the food was soaked with suspensions of tubercle bacilli the percentage of infections of the cervical glands was considerably increased. We may suppose that the child inhales occasional tubercle bacilli which reach the bronchi and from thence are carried to the tracheobronchial glands, and that he swallows tubercle bacilli from time to time, some of which may reach the cervical glands, while others may chance to pass through the stomach, especially when it is disordered, and infect the mesenteric glands from the intestine. When opportunity for massive infections is absent it is reasonable to suppose that the acquisition on the part of the child of a sufficient number of tubercle bacilli to produce infection is often a protracted process. This is favorable in so far as it tends to avoid an overdose of tubercle bacilli before immunity has been inaugurated, unfavorable as respects the formation of aggregations of tubercle bacilli.

Beitzke,[4] wishing to determine whether tubercle bacilli are disseminated by the blood even in the latent stage of tuberculosis, inoculated into guinea pigs glands from 27 children one to fifteen years of age, the bodies of whom presented no trace of tuberculous disease at autopsy. Nine cases were positive for tubercle bacilli. Of these in two cases the cervical, tracheobronchial and mesenteric glands contained tubercle bacilli, in one case there were tubercle bacilli in the tracheobronchial and the periportal glands, in another in the periportal and axillary glands. In four the cervical glands were alone affected, and in one the tracheobronchial glands. From these results Beitzke concludes that hematogenous dissemination of tubercle bacilli must be exceptional in the latent stage of tuberculosis, for, if it were not, the axillary and inguinal glands would have been infected, whereas the axillary gland was only infected in one doubtful case and the inguinal glands were uniformly negative.

This argument is convincing as to the improbability of hematogenous dissemination of tubercle bacilli during the stage of latency. But Beitzke supposes that the tubercle bacilli, when more than one gland contained them, had passed from one to another gland by way of the lymph vessels. There are obvious difficulties in this assumption. If not perfect, the lymph glands are at least good filters. We may expect that small collections of tubercle bacilli, such as remain latent in cases like those of Beitzke, will be retained by the lymph glands. We prefer, then, to assume that the tubercle bacilli in the various glands were not derived in such cases from the collections in any of these glands, the infections were multiple from the onset, the collections entirely independent of one another. So long as all the collections are below the threshold of infection there is no systemic infection. The largest collection of tubercle bacilli, other things being equal, will first reach the threshold, the body will become infected from it and thereby there will be inaugurated an immunity which by increasing the resistance of glands harboring the other latent collections may keep these collections permanently latent, perhaps ultimately destroy them.

The same influence of immunity in restraining the growth of the minor foci may be apparent after manifest tuberculous lesions have developed. For example: when hematogenous dissemination of tubercle bacilli has begun at an early stage of systemic infection, the lung as Ranke[5] remarks, is the first capillary network to catch the circulating bacilli. For mechanical reasons, therefore, the tracheobronchial glands become secondarily flooded with tubercle bacilli whatever the location of the primary lesion. In these glands, if the immunity is still rudimentary, the greatest conflict takes place. If a more perfect immunity results therefrom small manifest foci elsewhere are restrained by it, and if these foci are contained in well developed glands like those of the mesentery (which glands, as Beitzke says, are much exposed to bacteria and at an early time acquire a certain insensitiveness to them), the foci will probably become arrested, perhaps healed, leaving hyaline foci such as have been demonstrated by Warthin.[6] Manifestly if sensitization of the organism led to increased reaction to previously existing collections of tubercle bacilli in such conditions as those just considered, the picture of early tuberculosis would be very different from that with which we are familiar. The facts of observation would seem rather to favor the view that under the influence of immunity multiple collections of tubercle bacilli for the most part fail to develop macroscopic foci, so that the largest focus alone may reach the stage of manifest tubercle and may give the impression of a single infection. If, however, immunity fails at a later time such latent collections may increase by multiplication of bacilli and result in the production of manifest tubercles and these may then be considered to be superinfections of a later date than that of the primary focus.

The evidence that tubercle bacilli lying latent to macroscopical examination in the glands have caused a systemic infection is twofold: first, the positive reaction to tuberculin by cutaneous and intracutaneous methods; second, histological changes manifested by a primary swelling with secondary contraction and induration of the gland tissues, "lymphoid hyperplasia." In the most favorable cases the tissue changes probably do not pass beyond the stage of hyperplasia with secondary fibrous contraction. Such cases probably acquire the highest immunity and pass through life without undergoing any further extension of tuberculous processes. In a large majority of cases, however, whether because the original infections have been too large or because of lapses in immunity the tuberculous infection goes on to the production of the manifest tubercles so often found at autopsy even in the apparently non-tuberculous subject as caseous or calcified foci.

Tendeloo has shown that if chemical irritants such as formic acid, silver nitrate, or balsam of Peru are injected into the lung substance an inflammatory focus results which is made up of three zones: a zone of fibrinous inflammation, with leucocytes, at the center; next a zone of serous inflammation, and last a zone of proliferation of connective tissue. The two inner zones are the result of the poisonous or irritant action of the introduced substance, the outer zone is the result of a stimulus to growth by the irritant now diluted in its dissemination from the point of introduction. This inflammation from a chemical irritant with its various zones much resembles the inflammatory phenomena characteristic of an active tuberculous focus. We may say also, in the case of the latter, that the inner zones of the tubercle are largely the result of the concentrated irritant and inflammatory effect of the toxic substances of tubercle bacilli, while the more diluted noxæ produce a stimulus to proliferation of the outlying tissues, the effect of the concentrated antigens being in great measure at least to produce a passive injury of the nearer cells. As Meissen puts it, the pneumonic inflammation is an "actio" of tubercle bacilli, the connective tissue proliferation the "reactio" of the organism. By the proliferation of cells stimulated by the products of the tubercle bacillus small collections of tubercle bacilli are confined among strands of contracting fibrous tissue, small tubercles may be interwoven and obliterated by fibrous threads, larger tubercles are surrounded by a firm fibrous capsule. The ability to develop abundant fibrous tissue in the presence of the tubercle bacillus is characteristic of the more or less immune body.

The cell by contact with the products of the tubercle bacilli acquires the power of secreting ferments adapted to the digestion of the foreign albumin. Under the most favorable conditions, as in the peritoneum of the immune, such ferments may cause extensive bacteriolysis. The fact that virulent tubercle bacilli are eliminated by immunized animals which remain uninjured by the large so-called reinfecting doses is, however, sufficient evidence that lysis of tubercle bacilli is not a prominent feature in the maintenance of immunity. The power of the cell to form ferments against tuberculous albumin is more a weapon of defense than of offense, that is, it suffices to check the multiplication of tubercle bacilli rather than actually to destroy them. Like all ferments, the ferments of the immunized cells act best on traces of the antigen. The poison which in high concentration destroys the life of the body cells impairs the vitality of cells when present in less fatal concentrations. For these reasons the tuberculous focus exercises an unfavorable influence upon the neighboring living tissue. Immunity may be high enough to prevent all extensions at a distance, but its processes may not be able to check extensions in the immediate vicinity of the focus. In any case large tuberculous foci, even large collections of tubercle bacilli artificially introduced, are not destroyed. The antibodies of the circulating fluids and the ferments of the surrounding cells are powerless against large aggregations of the tuberculous antigens as they are against large aggregations of other antigens (abscess, gumma, etc.).

The encapsulation by which a tuberculous focus is shut off is a mechanical defense. Yet in the last analysis the defense against extensions of tuberculosis is not mechanical. Wherever living tissue is found there are lymph channels through which antigens and antibodies pass. Failure of immunity is often first manifested by the softening and breaking down of the fibrous envelope of a tubercle, and at autopsy we sometimes see a fresh tubercle in the center of a contracted and indurated hilus gland, or find multiple fresh tubercles strung like beads through the oldest and most massive fibrous trabeculæ of upper lobe lesions. No mechanical defense is efficient against tubercle bacilli unless supplemented by the presence of defensive substances in the circulating fluids. Since the success of restraining efforts is governed by the quantitative relations of antigen and antibody, it is to be expected that the larger foci will be restrained with the greatest difficulty and the conclusion is justified that in partial failure of immunity the extension of tuberculosis will first take place from a large focus. And we should also expect that while the body retains any considerable portion of its immunity all subsequent extensions of the tuberculous process would be able to advance only under the protection of the toxic substances given off by preexisting lesions, that is, by continuity or in the immediate vicinity of such lesions. Furthermore, if concentration of toxic products is a necessary condition for extension under the supposed conditions, such extension will take place solely or by preference in parts of relative immobility in which the requisite concentration can be maintained.

An apparent exception to the law that extensions occur only from large lesions by continuity is furnished by miliary tuberculosis which in adults is almost always a secondary extension and not infrequently occurs in cases in which isolated or well-localized tuberculous lesions of long standing would seem to show the existence of an immunity. It was formerly believed that the mere presence of tubercle bacilli in the circulating blood would suffice to create tuberculous foci wherever the bacilli might chance to lodge. The facts of tuberculous bacteriemia in man and in animals and of the elimination of tubercle bacilli by the bile and other secretions dispose of this theory. For the development of miliary tuberculosis in the immune some additional factor must be necessary. We find this factor in the poisonous products of tubercle bacilli. Miliary tuberculosis, as is generally recognized, proceeds (in the immune) from the irruption into the blood stream of tubercle bacilli contained in a caseous gland or other caseous focus which has become adherent to the walls of the blood vessel. But from a softened focus there are poured forth not only tubercle bacilli but fragments of cheesy substances. The infection is produced by emboli which might be called ambulant tubercles. Lodgment of these emboli produces new foci in which the tubercle bacilli are aggregated from the outset and in which their growth takes place under the protective influence of the toxic products from the original lesion, favored, no doubt, by the overwhelming of the reactive powers of the infected organism from the sudden liberation of large amounts of toxic substances. Miliary tuberculosis of the partially immune subject is therefore not an exception to the rule that secondary tuberculous foci are formed by extension from a large focus under the protection of its toxic products, but is on the contrary an illustration of that rule.

We may summarize the foregoing as follows: Under natural conditions tubercle bacilli enter the body one by one. The primary infection is produced by an aggregation of tubercle bacilli. First infections may be and probably usually are multiple. But immunity tends to keep small collections of tubercle bacilli latent and to isolate and make fibrous small tubercles. Immunity is well-nigh absolute under conditions in which the antibodies preponderate over the antigens, hence at all parts of the body remote from large tuberculous foci. But where the antigens preponderate, as in the vicinity of large foci, immunity is most severely taxed. If immunity fails sufficiently to permit any extension of the original tuberculous process such extension will first proceed from a large focus by continuity and into relatively immobile parts. So long as a fair degree of immunity persists, the further progress of the disease will likewise be only by continuity from previous lesions and under cover of the toxic products of the tubercle bacillus.

Having thus outlined the conditions which appear to govern the extension of tuberculosis in the relatively immune body, it now remains for us to inquire how far these conditions may be found to apply to the progress of pulmonary tuberculosis.

The lung is the only organ in the body which functions more actively in one part than in another. In the infant, in whom the apices are not yet fully developed and whose elastic thorax expands practically as well in one part as in another, the distinction as to activity of function is but little apparent. In the mature adult, especially in the sedentary individual, the apices hardly move at all in ordinary breathing. The transformation of the cell which means immunity is a function of its nutrition, which nutrition is dependent upon functional activity and the vascularity which accompanies functional activity. Therefore, if the lung participates in the general immunization of the body against tuberculosis, manifestly the acquired immunization will be greatest in the most actively functioning portions. The apex will fall relatively behind the other parts of the lung so far as the development of acquired tuberculosis is concerned. The stiffer the thorax and the less the respiratory activity of the apex, the more definitely does the latter become the part of least resistance, the more likely is it that tuberculous processes will localize themselves there.

Chronic pulmonary tuberculosis typically begins at the apex or the upper part of the upper lobe, a region of slight mobility, and advances downward. The progress of the tuberculous process in the relatively immobile parts is manifested by increase in the number, later by the coalescence of tubercles, finally by cavitation. In relatively acute cases of upper lobe involvement the entire lobe may break down into a cavity. In cases of less severity and acuteness in which the course of the disease can be traced, we note that as a rule the disease extends downward over the anterior or posterior surface of the lung. The progress, except as to increase of the original focus, is from the relatively immobile toward the more mobile portions. It is a development by continuity in the sense that new tubercles form only in parts near enough to the older foci to be under the influence of their poisons in concentrated form. Until the region of the third rib is reached anteriorly the course of the tuberculosis is relatively slow, the tubercles are large; below the third rib the progress is relatively rapid, the tubercles are small and have a certain regularity in their distribution, the superior tubercles are larger than the inferior, cavities are small or are absent if pleural adhesions are not well marked. The base of the lung presents two types as respects extension of tuberculosis. In the first type it is free of tubercle, at least in its superficial portions. In this type there are no adhesions over the lower lobe. But if well-marked adhesions are present, and especially if the plural cavity is completely obliterated, we may have quite a different picture—the second type. Large tubercles are present, irregularly interspersed between trabeculæ of fibrous tissue, the process suggesting that typical of the upper lobe. Or in more acute cases, the lower lobe may be the seat of enormous cavities. Now in these two quite distinct types when the clearness of the picture is not blurred by intercurrent disease, miliary tuberculosis, aspiration pneumonia, etc., it is apparent that the differences observed are due to the presence or absence of normal mobility. As the tuberculosis progresses downward in the non-adherent lung it encounters more and more mobile parts. At the apex the respiratory movements are slight, tuberculous products stagnate, affect strongly the vitality of the immediately contiguous cells, tubercles grow by coalescence; in the more mobile parts, the lower part of the upper lobe, the upper part of the lower lobe, the motion of the lung distributes tubercle bacilli and their products more freely. The cells are still attacked by a sufficient concentration of tuberculous poisons to permit tubercles to form, but the tubercles are more discrete and smaller, for comparatively stagnant poisoned lymph no longer overwhelms the vitality of the neighboring living cells. Finally the region of greatest mobility is reached, the region under the influence of the diaphragm as well as of the freely moving lower ribs. Here the respiratory movements are so powerful that the poisons of tubercle are scattered and diluted. They no longer maintain the requisite degree of concentration, tubercle bacilli are no longer able to proliferate, tubercles do not form.

We recognize, then, three regions in the lung: the region of relative immobility, the region of moderate mobility, and the region of great mobility. In the first region stagnation of lymph favors large tuberculous lesions of slow progress; in the second region, motion of the lymph favors small lesions of rapid growth. In the third region, withdrawal of tubercle bacilli and their products by inspiratory suction prevents the formation of lesions. If the movements of the lung are restrained by adequate adhesions these differences disappear.

Ghon[8] in 644 autopsies of children found 184 cases of pulmonary tuberculosis. In 170 of the 184 cases there was a lung focus, in 14 cases there was not. Involvement of the bronchial glands was present in all of the tuberculous cases. The primary lung focus was usually small. The regional glands were preponderatingly affected. In many cases the size of the lesion in the glands exceeded that of the parenchymatous focus. There was sometimes excessive caseation of the glands. As for the distribution of the foci (which were usually single) the right lung was affected more than the left, there were more foci in the right upper than in the right lower lobe. The majority of the foci were near the surface or subpleural. Pleural adhesions were generally present over the lesion

or elsewhere. Küss, from whom Ghon makes extended citations, found on the other hand in his large material that the right and left lung were affected equally and that the lesions decidedly preferred the lower lobes. He agrees with Ghon as to the generally subpleural location of the lesions and as to the frequency of pleural adhesions. Comparing the results of the two authors, it would appear that the only law manifest in the distribution of the lesions is their usually subpleural location. Their distribution as to lobes would seem to be a matter of chance. Both authors think their findings to prove the aerogenous nature of the infection, and consider the parenchymatous focus to be the primary focus of the tuberculous infection. A critical examination of these observations with respect to their bearing upon the aerogenous theory is not within the scope of this paper. The important point with reference to the discussion in hand is the fact that parenchymatous foci of the lungs of whatever origin, occurring in subjects who from their youth could probably have had no well developed immunity, are found in any portion and usually the more mobile portions of the lungs.

In contrast with these results in the non-immune child are the well-known observations of Birch-Hirschfeld.[9] This author found that tuberculosis of the lungs in the first stage presents itself as a tuberculous ulceration of the mucous membrane of a medium sized apical bronchus. This first tuberculous focus is, he says, as a rule rather large (often the size of a hazel nut). It lies beneath the surface and produces at first no change of form of the surface of the lung. The visceral pleura is smooth and free from adhesions. Of 32 observations of incipient tuberculosis, 28 agreed in having the seat of the tuberculous focus in the wall of a medium sized bronchus (so called branches of the third to fifth order, regarding the chief bronchus of the lobe as of the first order). The ramifications of the posterior apical branch were especially affected. Birch-Hirschfeld regards these findings as demonstrating the aerogenous origin of pulmonary tuberculosis, and his observations have been frequently referred to by later writers as affording a proof of this theory. Unfortunately, Birch-Hirschfeld nowhere states the age of his subjects. There is, however, reason to believe from internal evidence that they were adults. Comparing his results with those of Küss and Ghon, we find larger, more deeply situated lesions and a preponderating location in least mobile parts of the lung and upon the bronchi, as contrasted with small lesions located by chance in the parenchyma, but usually subpleural. There would seem to be no doubt that Birch-Hirschfeld's foci are the primary manifest pulmonary foci of more or less immune individuals. His observations are of great importance as showing that the primary manifest focus in the pulmonary tuberculosis of the immune is usually situated in the least mobile tissues (the bronchi) of the least mobile part of the lung, and comparatively near the surface but not subpleurally.

It may be interesting to inquire if there are physiological reasons why the part of the upper lobe in which is found the primary focus of Birch-Hirschfeld should afford an especially favorable opportunity for the development of the first manifest tuberculous lesion. To do this will necessitate a brief consideration of some points in the anatomy of the lung and the mechanics of respiration.

The lung is an elastic organ, but not perfectly elastic. The superficial parts of the lungs expand consequently more than the underlying portions of the same lobes. The parts farthest from the hilus expand most, the lower lobes expanding much more than the upper. From a maximum of approximately 3 inches in the complemental spaces in the axillary line, the expansion diminishes gradually to a nominal amount in the paravertebral portion of the upper part of the upper lobe. The imperfect elasticity of the lung is due not only to the character of the parenchymal tissues but also, as Tendeloo[10] has pointed out, to its non-homogeneity from the presence of bronchi and vessels. The large bronchi elongate and retract during respiration, to an extent progressively less as the hilus is approached. The bronchioles near the surface are more freely movable and not only elongate but expand in inspiration. The direction of the bronchi is approximately perpendicular to the thoracic wall. They occupy the center of the lobes and of the lobules traversed by them. The expansion of the air cells is greatest at the periphery of lobes and lobules and diminishes progressively towards the center. It follows then that the bronchi always occupy the least mobile portions of the lobes and lobules through which they run.

During inspiration the arteries are lengthened, the blood within them is sucked peripherally and is accommodated in the widening and lengthening capillaries, so that notwithstanding the theoretical acceleration of the blood current due to aspiration the pressure within the capillaries is lowered during inspiration. In the veins the suction of inspiration effects a retardation of the centripetal flow. The blood and lymph of the cortical portions of the lung are actually carried outward in inspiration, the lengthening and widening of the venules and lymph vessels effecting a lowering of the pressure within these vessels as in the arterioles and capillaries.

The flow in the veins being more rapid than the respiratory movements, the rapidity of the venous current is simply slowed by the movements of inspiration. Not so with the lymph which originating from the blood of the capillaries has as its impelling force the secretory pressure and in the upper lobe the lymphostatic pressure. We may reasonably suppose that the effect of inspiration upon the lymph capillaries and smaller lymph vessels of the superficial parts of the lung is to produce an actual reversal of the lymph current. The more centrally situated portions of the lymph vessels contain lymph which under the influence of previous propulsive factors is progressing towards the hilus, and in the larger vessels is prevented from retrograding by numerous valves (the fact that there are no valves in the pulmonary veins while the lymph vessels are well supplied with them is apparently a proof that the circulation of the veins is not subject to stoppage by respiratory influences, but that the reverse is the case with reference to the lymphatics). There will therefore be a region in the course of the lymph vessels where their contents will tend to be drawn both forward and backward, that is, will remain stationary. In the actively moving lower lobe the force of lymph flow in both directions being well marked such pause will be but momentary. In the less ample and forcible inspiration of the upper lobes with their scantier lymph flow corresponding with their lesser vascularity and functional activity, the suction backward and the forward advance of the

lymph stream are relatively feeble, there will be a pause of some duration in what we may call the region of intermittent stoppages. For the immune subject in whom colonization of tubercle bacilli can only take place under conditions most favorable for their growth, the region of intermittent stoppages will afford the best, perhaps the only opportunity for infection, the checking of the lymph flow enabling tubercle bacilli to leave the closed lymph channels and immigrate into the lymph spaces. Hence the so-called primary focus, the first tuberculous lesion of the clinician, usually forms, in the relatively immune subject, in the upper lobe on the 3d to 5th ramification of the bronchus of Birch-Hirschfeld or in the neighboring parenchyma, near the surface of the lung but not upon it, the precise depth depending upon the amplitude of respiratory movement of the upper lobe in the given case.

Animal experiment has shown beyond a doubt that in inoculation with tubercle bacilli whatever route may be chosen the tracheobronchial lymph glands usually become infected. If this is true in primary infections of animals, it is still more true in the aftercourse of infections of the human subject. Albrecht and Arnstein[11] examining the bodies of 100 children from 6 to 16 years of age, who died of various diseases, found clinical tuberculosis present in 38. Of the remaining 62, in 36 tuberculosis was found in the tracheobronchial glands by macroscopic examination. This left 26 cases of the 100 in which there was present no visible evidence of tuberculosis. The tracheobronchial glands of these cases were subjected to histological examination with the result that in 13 cases tuberculosis was found, thus leaving but 13 cases of the 100 which were negative under inspection, macroscopic or microscopic. The authors divide their cases by periods. Of the period 6-10 years, 51 out of 61 children had tuberculosis of tracheobronchial glands or had manifest tuberculosis in which tuberculosis of the tracheobronchial glands may be assumed, or 83.6 per cent. Of the period 10-16 years 36 out of 39 had tuberculosis of the tracheobronchial glands or manifest tuberculosis, or 92.3 per cent. Hamburger with the Stich-reaction found an average of 82 per cent. of children to react. The figures of Albrecht and Arnstein agree well with Hamburger's, for the latter found for the period 7-10 years about 71 per cent. positive to tuberculin, for the period 10-14 years 94 per cent. in clinically not manifestly tuberculous material, as compared with Albrecht and Arnstein's 83.6 per cent. for the period 6-10 years and 92.3 per cent. for the period 10-16 years. It appears then that in children the reaction to tuberculin is practically equivalent to tuberculosis of the tracheobronchial glands. But since it is well known that adults are found to be infected with tuberculosis in a percentage increasing with age and that the implication of the respiratory system becomes more and more constant, it is hardly too much to say that the civilized adult almost without exception has a tuberculous infection of the tracheobronchial glands. The reason for the preponderating involvement of these glands has been alluded to in the foregoing. We are now especially concerned with the fact that the tracheobronchial glands contain the most constant and, it is fair to assume, the largest depot of tubercle bacilli and their products which is to be found in the body of the more or less immune individual. On theoretical grounds therefore we should expect, in conformity with the law already referred to, that if the immunity of the individual is diminished to the extent of permitting any extension whatever of tuberculosis, such extension will occur from the tracheobronchial glands.

The *x*-ray appears to show that this is the case. Cole[12] states that radiographic examination of incipient cases of tuberculosis indicates that in a very large percentage of cases the lesion of the root is more extensive than the parenchymal lesion, and so frequently do radiograms show a distinct lesion at the root with no parenchymal involvement that it is reasonable to assume that it extends from the root to the parenchyma. Radiating from the root to the apex in the adult and to the base in children may be seen infiltrations in and around the walls of the bronchi, the air cells supplied by these bronchi are infiltrated with isolated or conglomerate tubercles. There may be a diffuse fibrous growth extending from the root. There may be infiltration in and around the large bronchi without thickening at the root and without parenchymal involvement, and there may be a more or less extensive exudative process.

With the improvement of technique in *x*-ray work it is coming to be more or less of a commonplace that adults present in a greater or less degree evidences of healed tuberculous processes which are manifested by thickening of the normal lines radiating from the hilus. With commendable conservatism many *x*-ray operators hesitate to consider these thickenings as evidence of tuberculosis except in the presence of more or less sharply circumscribed spots or dots which are considered to be tuberculous foci and which are very common in the vicinity of the hilus. Even without these dots, however, a thickening of the radiating lines which is not universal throughout the lung and especially thickenings confined to the less mobile parts of the lung are usually characteristic of a present or past tuberculous process. In view of the frequency of tuberculous involvement of the tracheobronchial glands, it is evident that the liberal interpretation of these changes as of tuberculous origin is more likely to be the correct one. Cole's description which has been quoted in part above presents a general picture. He is not concerned with the lung of the more or less immune individual in any especial way. But it is evident that the more immune the subject the less characteristic the picture because the more closely it is confined to purely fibrous processes. Limiting ourselves to the case of the immune individual whose immunity has relaxed sufficiently to permit tuberculous extension, but solely under conditions and at places most favorable for the growth of tubercle bacilli, how may we conceive of the process, first, as respects the deeply situated parts of the lung, secondly, as respects extension to the superficial parts?

We have the following laws to guide us: First: extension will occur first and in case of high immunity probably solely from the lymph gland which contains the largest collection of tubercle bacilli and of the products of turbercle bacilli. Second: extension will occur in tissues most flooded by the products of tubercle bacilli. Third: it will occur in the parts which best permit the multiplication of tubercle bacilli, *i.e.* the most immobile parts. By the first law a tracheobronchial gland will usually constitute the starting point of the infection. Holding the largest collection of tubercle bacilli and of their products, the tuberculous process has

been held in check there with the greatest difficulty by the immune processes. Tubercle bacilli escape in lymph poisoned by their products into the adjacent tissues and the tuberculous process spreads by their proliferation. The direction of extension seems to be at first usually downwards, perhaps influenced to some extent by gravity. The paravertebral portion of the lower lobe is the least mobile portion of this lobe. The course of the infection will be chiefly directly downwards. The infection cannot of course extend against a strong centripetal lymph current. But we must not think of the lymph vessels as large. According to Bartels[12] the deep lymph vessels of the lung are situated in the walls of the bronchi and along the branches of the arteries and veins. The smaller arteries and veins are accompanied by only one lymph vessel, but the lymph vessels of the bronchi are five or more in number and run along the posterior wall. There is a plexus of lymph vessels about each bronchial cartilage. When we consider that the flow of lymph from healthy lung is not abundant under ordinary conditions, we shall find no great difficulty in believing that one or more of the five lymph trunks of a bronchus will be practically empty or at least not contain so powerful a stream of lymph as to present any insuperable obstacle to the distal extension of the tuberculous process. This is a question which must be left to further investigation. But there is no reason why the tuberculous process cannot spread through the lymph capillaries and plexuses of the bronchial tubes and blood vessels and of the immediately adjacent parenchyma. If it attempts to extend laterally into the air cells the tubercle bacilli and their products are dissipated by the motion of the lymph and the respiratory activity of the parts forbids the multiplication of the bacillus which by supposition can only prevail against the immunity of the body when aided by a relative immobility. The process is therefore confined to the immediate vicinity of bronchi and blood-vessels. A factor which tends to prevent widespread stagnation of the lymph with resulting large caseations is the aspiration from the large lymph vessels, the current of which is proceeding towards the hilus. Any effusion therefore which reaches a vessel communicating with a large lymph vessel is drawn into the centripetal lymph stream. The tuberculous process is thus necessarily confined closely to the parts of least mobility because an accumulation of toxic products sufficiently strong to overcome the immunity can only collect in these parts. It is a process therefore of slow growth and well drained of excess of lymph. Since it is thus limited to small vessels there is no great aggregation of tubercle bacilli anywhere. The effect upon the organism is therefore predominatingly or solely to produce a proliferation of fibrous tissue. Tubercles do not form except perhaps in lymph glands, where the conditions permit larger aggregations of tubercle bacilli. Before the process has proceeded far in a downward direction the motion of the lung under the powerful influence of the diaphragm becomes well marked. The bronchi begin to expand and elongate noticeably. They no longer afford the necessary repose in their lymph capillaries. It is even more difficult than before moreover for the tuberculous process to extend laterally on account of the more vigorous respiratory movements. The tubercle bacilli may advance to the region of intermittent lymph stoppage, but the conditions here are not favorable for the formation of large foci, of manifest tubercles, because the stoppage is but a momentary pause between the ebb and flow of a flood of lymph. Any tubercle bacilli which penetrate beyond this region are aspirated away by the suction of inspiration, scattered, and returned to the hilus by the centripetal lymph flow. The downward extension of the tuberculosis is therefore soon checked. It has been confined in the class of cases under consideration to a chronic peribronchitis productiva, leading to a thickening of the bronchial envelopes and of the peribronchial tissues which manifests itself to the *x*-ray by a darkening and thickening of the normal lines, the markings diminishing toward the periphery of the lung and disappearing before the superficial part of the lower lobe has been reached. In less resistant cases the process may extend outward as well as downward, in the direction of the complemental space, and manifest foci, usually in lymph glands, may show themselves to the *x*-ray as dots or larger spots along the thickened lines and especially at bifurcations of these lines. But in this direction, too, the process is confined to the deeper parts of the lung and the evidences of it fade out before the freely moving superficial parts are reached.

For extension laterally from the hilus the conditions are still more unfavorable. The bronchi are smaller, hence the more mobile parts are even more quickly reached and the process is only indicated by a darkening which extends a short distance with perhaps involvement of the lymph glands shown as before by more or less sharply marked roundish shadows. The form of tuberculosis so far manifested is not of a formidable type, since large tubercles have not been developed. With the supposed degree of immunity, the stimulation afforded by the restricted and little acute but at the same time rather extensive tuberculous process (we may conjecture) raises the immunity to a degree sufficient to inhibit further activity on the part of the tubercle bacilli. The induration progresses to its maturity without check. There is no further extension of tuberculosis perhaps for years. If the tuberculous process is arrested for a long enough time a local immunity develops which with the crippling of the lymph-capillary system due to the old inflammation is sufficient to prevent permanently any renewed tuberculous activity in a downward or outward direction from the hilus.

So far the process which we have outlined has run its course in early life. Supposing now that the patient has reached or is approaching years of maturity and that the immunity has again begun to fail. The tuberculous extension of childhood has naturally taken its origin from the glands which were supplied by lymph from the largest and most active parts of the lungs and which therefore might be expected to receive the largest numbers of bacilli from the circulating blood. But when adult age is reached these glands have undergone a transformation. Under the revived immunity following the arrest of the active process they have become indurated, calcified, the tubercle bacilli which they contain are imprisoned, access to the glands from the lower lobe has become difficult on account of the indurative changes about the larger lymph trunks. Tubercle bacilli carried to the hilus now reach glands higher in the chain, formerly less severely affected, in which the tuberculous process has not yet run its course. Extension now takes place from the superior glands, in the direction of

the upper lobe. The tuberculous process advances as it did in the lower lobe, except that now it is against gravity. The lymphostatic pressure is now positive. The lesions are better drained than before and are therefore even more closely confined to the parts of least mobility, the bronchi. But on the other hand the tuberculous process is now advancing into a region of less mobility. The paravertebral portions are still the regions of least mobility, but the entire upper part of the upper lobe is much less active than the lower lobe. Hence according to the activity of the tuberculous process and the mobility of the upper lobe there will be a greater or less tendency to diverge from the regions of least to those of little mobility. The process may be shown by the *x*-ray as mainly vertical lines proceeding to the posterior and superior portions of the upper lobe or there may also be seen lines radiating toward the shoulder joint. When the tuberculous process approaches the superficies of the lung it may terminate in two ways. If the subject is still young and active, the chest flexible, and the immunity relatively high, the region of intermittent lymph stoppage affords no very favorable place for development. The bronchi expand and elongate. They no longer offer a suitable breeding ground for tubercle bacilli. The bacilli and their products tend to become dissipated. They are sucked toward the pleura and form small tubercles or succeed only in exciting indurative processes in the superficial lung. As before, a revival of immunity may cause arrest of tuberculous activity. The apex becomes indurated. The condition present is the abortive tuberculosis of Bard. If, on the other hand, the subject is of a sedentary habit, the thorax stiff and the immunity less good, the respiratory changes of the apex will be minimal, the bronchi will move hardly at all in respiration, the suction toward the pleura will be slight, the intermittent lymph stoppages prolonged. All the conditions will favor the stagnation of lymph in this region, the accumulation of toxic products, the proliferation of tubercle bacilli. A manifest tuberculous focus will form at the point of election of Birch-Hirschfeld on the smaller bronchi, or in the adjoining parenchyma. The tuberculous process has emerged from the condition of a clinically latent productive tuberculous peribronchitis into that of a clinically manifest caseous tuberculous focus and the subsequent possibilities are familiar.

We have followed a process which exemplifies the laws of extension of tuberculosis in the immune as laid down in the first part of this paper. Starting from the largest collection of tubercle bacilli and their products the process has proceeded by continuity under cover of the toxic products of tubercle bacilli through the regions most favorable by reason of their immobility for the growth of the bacillus to the superficial region of least mobility and of least perfectly developed immunity in which alone large parenchymatous tuberculous foci are able to develop in the highly but not perfectly immune individual.

The apex of the lung is the seat of the first manifest focus in the pulmonary tuberculosis of the relatively immune subject, because its slight mobility permits the invasion of a peribronchial tuberculosis which extends from the largest primary focus by continuity through relatively immobile parts.

# EXACT DIAGNOSIS BY ACCURATE INSTRUMENTS IN THE TREATMENT OF CATARRHAL CONDITIONS OF THE EUSTACHIAN TUBES AND EARS.*

By HAROLD HAYS, A.M., M.D.,

NEW YORK.

ASSISTANT SURGEON IN OTOLOGY, N. Y. EYE AND EAR INFIRMARY; ASS'T OTOL. AND LARYNG., CITY HOSPITAL.

In the treatment of catarrhal conditions of the Eustachian tubes and ears, the otologist no longer finds it necessary to work along empirical lines and to confine himself to the haphazard methods of the

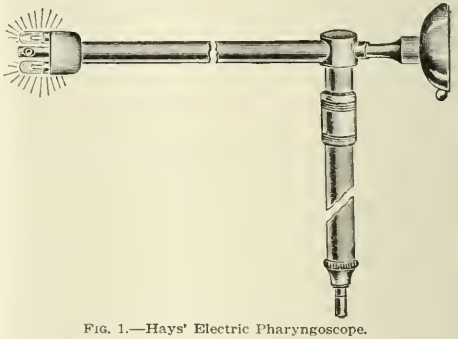

Fig. 1.—Hays' Electric Pharyngoscope.

older days. During the past decade the advancement of exact diagnosis has been exceedingly rapid, due mainly to our ability to apply electrically lighted instruments to those parts which at one time had to be treated in the dark. There are many men who still adhere to the older methods and who refuse to adopt any of the finer instruments. These men not only fail in the treatment of their cases, but are unable to find out that primal cause which eventually results in such a disastrous ailment as deafness. I have stated over and over again in previous papers that there is nothing more distressing than deafness which is allowed to go on year after year and which the patient thinks cannot be stopped or cured, because he has been unable to find the man who is willing to take the time and trouble to get at the basic factors in his condition. Not by

*Read before the Harlem Medical Association, October 1, 1913.

any means do all cases of so-called catarrhal deafness arise from the same cause. Patients must be treated individually for these conditions, and the treatment must be based upon definite etiology the same as in any other disease.

I shall in this paper describe the various newer instruments for diagnostic and treatment purposes, which have been invented within the past six or seven years, and show how they can be applied to the treatment of catarrhal conditions of the Eustachian tube and those parts directly affected by it.

In my desire to devise an instrument for the more exact view of the nasopharynx, early in 1909 I invented an instrument called the pharyngoscope, which I believe up to that time was the first instrument (with the exception of the so-called salpingoscope, out of which later arose the nasopharyngoscope of Holmes) which gave a symmetrical view of all parts of the nasopharynx and allowed of a thorough study of the tubes and the adnexa.

The pharyngoscope is an electrically lighted instrument, the optical portion of which is similar to the cystoscope. This telescopic portion is mounted in a flat metal sheath and on either side of the prismatic lens at the proximal end are two watertight electric lamps which when turned on to full incandescence give an excellent view of any part within the scope of the lens. At right angles to this flat piece is attached a handle on which is an electric switch for turning the current on or off. (Fig. 1.)

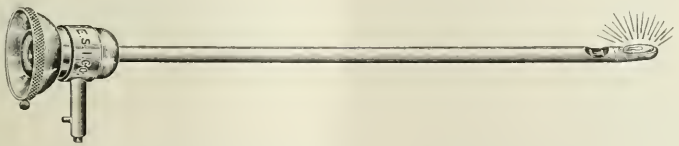

Fig. 2.—Holmes' Nasopharyngoscope.

This allows the instrument to be used as a tongue depressor. The distal lens containing the lamps and lens are placed behind the soft palate and when the mouth is closed by having the patient breathe through his nose, the nasopharynx shows up as large as a half dollar. In many cases where I have otherwise been unable to place the Eustachian catheter properly in position, by putting the pharyngoscope in the mouth and the catheter through the nose, I have been able to get it in an exact position under direct vision. I may say that by turning the lens down one obtains a very beautiful view of the larynx.

Although this instrument has met with a great deal of satisfaction in the hands of those who have had much experience with it there are some cases in which it is impossible to keep it in place for a sufficient length of time to obtain an exact view of the pathological condition around the Eustachian tube. I am happy to say that within the past few years Dr. E. M. Holmes of Boston has devised an excellent instrument called the nasopharyngoscope which overcomes this difficulty. This instrument, however, must be used through the nose instead of through the mouth.

The nasopharyngoscope of Holmes (Fig. 2) is a miniature cystoscope with the lens and lamp mounted at an exact angle so that one gets a very exact view of either Eustachian tube. The lamp is connected with a dry cell battery. After cocainizing the nostril which one wishes to enter the instrument is inserted into the inferior meatus until it reaches the posterior pharyngeal wall, when the lens can be rotated in any given direction so that the Eustachian tube of either side and the surrounding parts can readily be seen. By means of this instrument, instrumentation can be done on the opposite side in an exact manner, and also small operations in the vicinity of the tube, such as the removal of small adenoid masses in the fossa of Rosenmüller, can be performed. I believe that the nasopharyngoscope is exceedingly valuable in many cases where the throat of the patient is too irritable to stand any instrument, and I believe that Dr. Holmes should receive all the credit due him for getting out a precise aid to diagnosis, where others have tried before and failed.

The third useful instrument that I wish to present to you is a graded Eustachian catheter. The original instrument is the silver catheter of Yankauer, which I have had measured off with half centimeter markings. (Fig. 3.) This is a very simple device which is of exceeding value. Oftentimes the distance of the Eustachian tube from the edge of the nostril varies considerably. Unless one has a marked instrument of this kind it is often difficult for him to find the Eustachian opening exactly without the aid of some illuminating device. In a series of twenty-seven cases of which I have exact records, I have found that the distance from the Eustachian orifice to the center of the edge of the nostril varies from 8½ cm. to 11 cm., and that the distance on the right side varies from that on the left in many cases as much as ¼ cm. One must take into consideration in making these measurements that the curve of the Eustachian catheter must often be changed, and that therefore the difference in its supposed length varies. What is also of a great deal of importance is that it seems to be impossible to get instrument makers to make all of their catheters of the same length.

One of the commonest conditions seen in the treatment of catarrhal conditions of the Eustachian tube and middle ear, is a stenosis of the tube due to thickening of its mucosa from inflammation. A great advance has been made within the past few years in the treatment of such a stenosis by means of the ingenious instruments of Dr. Yankauer. I refer particularly to the applicators, bougies, and sounds. (Fig. 4.) The Yankauer applicator is a fine strand of steel wire at the end of which can be wound a small piece of cotton. This is put into a holder which is marked off into centimeters and half centimeters, so that one can gauge the exact distance he is in the Eustachian tube. The applicator is inserted into the catheter until the first mark on the holder appears at the proximal end. It is dipped into a solution of cocaine and adrenalin and then inserted into the nose and Eustachian tube, and is

gently pushed through the tube until it reaches the middle ear. The cocaine and adrenalin shrink up the mucosa to a certain extent and allow of a passage being made painlessly. Of course the length of Eustachian tubes vary, but his markings represent the average, and any one with the smallest amount of intelligence or experience can readily ascertain when he gets to the isthmus of the tube, after which it is safe to progress only a centimeter.

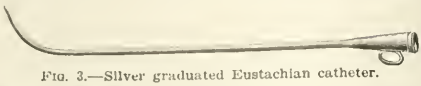

Fig. 3.—Silver graduated Eustachian catheter.

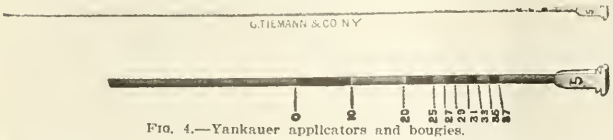

Fig. 4.—Yankauer applicators and bougies.

After the tube is once dilated in this way one can begin to insert suitable size bougies or sounds, which are marked in the same manner as the holder for the applicator. These are allowed to remain in place for a half hour or an hour, when as a rule the tube is more widely opened and very little pressure is needed with the Politzer bag to obtain the proper massage of the drum. Oftentimes the bougies and catheters can be seen through the drum membrane.

The newer forms of auroscopes are also of a great deal of value in diagnosticating conditions of the drum membrane. The best form that I have seen is an electric auroscope which is mounted on the handle of my pharyngoscope (Fig. 5), allowing one to use it with a great deal more exactness and gentleness than the older forms. At one side is an opening on to which can be fitted a small bulb for massage. This instrument is of a great deal of value in determining the amount of retraction of the ear drum or the amount of relaxation. It is extremely important in the treatment of so-called catarrhal conditions of the ear, to determine these factors, for at least 50 per cent. of the cases of catarrhal deafness are due to a relaxation of the ear drum rather than to a retraction or stiffening of the joint. The treatment in the two conditions is very different, and unless one determines this factor he is very liable to do a great deal of harm. I am in hopes that within the near future I shall be able to explain more fully the treatment of deafness due to relaxed ear drum.

A valuable adjunct to the auroscope is a new instrument which is not yet out on the market, but which I present to you this evening. It is called the Carroll tympanoscope. (Fig. 6.) This instrument is an auroscope mounted on a band which fits on the patient's head, so that it does not have to be held by the physician. A mirror reflects the image of the drum at right angles, and this image is magnified by a suitable lens so that the physician is able to see the vibrations of the ear drum as he massages the ear. In certain conditions this instrument is of extreme value.

The last instrument that I wish to describe I am in hopes will aid considerably in the exact determination of the amount of hearing in those cases of catarrhal deafness which it is difficult to ascertain by the ordinary means. The common test for hearing is by a tuning fork and the watch. The physician approximately guesses where the watch is heard, and approximately estimates the length of time the tuning fork is heard. For purposes of comparison day by day or week by week, this method is entirely inaccurate, and it is for that reason that within the past few months I have invented what I call an improved audiometer (Fig. 7), for the exact measurement of hearing.

The instrument consists of a scale, 60 cm. long, mounted on a suitable standard. The upper portion of this scale is a ratchet on which works a mechanical devise by means of a cogwheel. There is an opening into which can be mounted a watch (Fig. 8), preferably a stop watch, which is placed in contact with the patient's ear. The watch can then be moved silently away from the ear until the exact distance that the patient hears it is ascertained. If the distance is more than 60 cm. the apparatus can be moved an exact distance from the patient by proper markings on the floor. The watch hearing can be definitely determined within ½ cm. and duly recorded. The watch is then removed from its receptacle and a tuning fork (either 512 or 1024) mounted (Fig. 9). The second wheel controls a hammer (made to eliminate overtones) which is moved backward an exact distance by means of a strong spring. When the second wheel is turned the hammer strikes the tuning fork with the same intensity every time. When the tuning fork is struck the physician starts his stopwatch, and when the patient no longer hears it the watch is stopped. Thus there is an exact measurement of the length of time of hearing of the tuning fork. The hearing can then be expressed in the form of a fraction, the denominator being the number of seconds the patient hears the

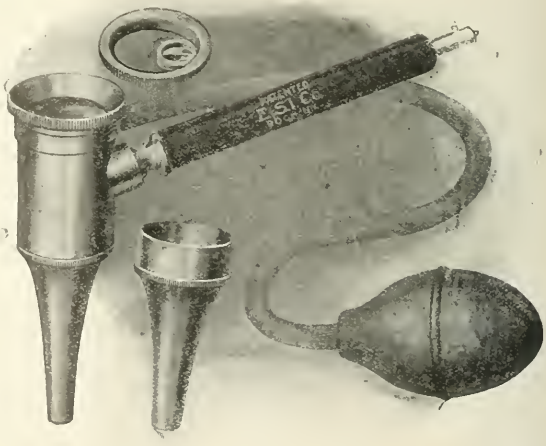

Fig. 5.—Electric auroscope.

tuning fork, and the numerator the number of centimeters distant the patient hears the watch. I have tried this audiometer on a number of patients within the past few months with very satisfying results,

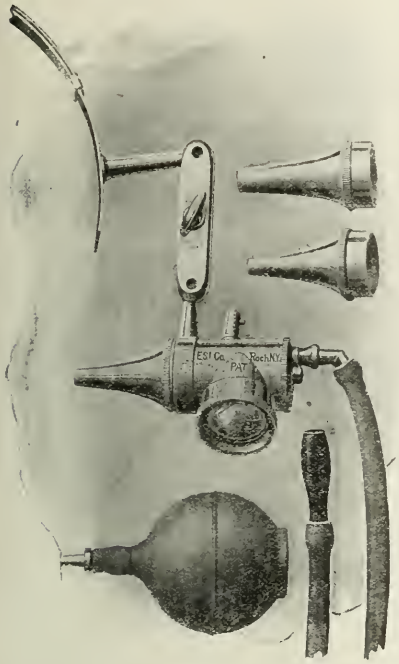

Fig. 6—Carroll tympanoscope.

and hope that others will meet with the same satisfaction with it that I have. Of course this does not take into consideration the finer tests for hearing which need special instruments, but which are of

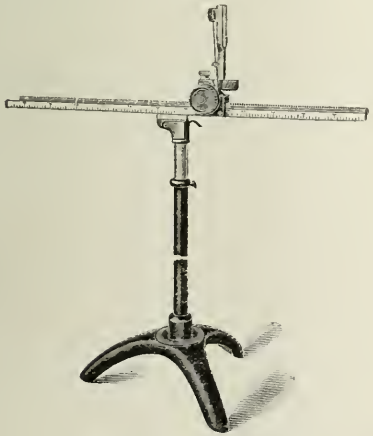

Fig. 7.—Hays' improved audiometer.

much more satisfaction to the physician than to the patient.

I believe that I have covered fully in this paper the newer diagnostic and working instruments that can be used in the treatment of ear conditions. This sort of treatment is far more exact than any that has heretofore been used, and the results are correspondingly better. It is not within the scope of this paper to record the results obtained. This is but the beginning of an awakening into the possibilities of completely curing or at least alleviating to a great extent that most distressing of conditions, catarrhal deafness.

## ADENOMA OF THE PROSTATE.

By EDWIN BEER, M.D.,

NEW YORK.

The following notes on benign growths of the prostate are based on 85 cases seen during the past two and a half years. Most of these were in the genito-urinary service of the Mt. Sinai Hospital. Of this series, 60 patients were operated upon by suprapubic route, the adenomata being enucleated, while of the remaining 25, 11 were too bad risks for a prostatectomy, 10 refused operation, and 4 had such slight symptoms that an operation did not seem advisable.

*Pathology of Prostatic Adenoma.*—For some time before the excellent work of Zuckerkandl and Tand-

ler many of us appreciated that the adenomatous masses arose in that part of the prostate that lies above the ejaculatory ducts. These investigators showed by beautiful anatomical studies that this conception was correct, and that the growing adenomata gradually compressed the rest of the gland so that it became a flattened-out shell, which is so regularly seen in cutting into the gland in the perineal operation. Whether they are correct in calling this part of the gland above the ducts the middle lobe has not been determined, as work by Lowsley goes to show that embryologically what lies above the ducts is made up of the two lateral and the middle lobes. This interpretation fits in very well with what I have seen in the cases studied by me. In a small percentage of cases there are adenomata which arise from the so-called Albarran glands, and which may grow as large as pears, projecting into the bladder and acting as true ball-valves.

As the obstruction to the outflow from the bladder becomes more and more marked the bladder becomes hypertrophied and trabeculated, pouches form and residual urine collects. This gives infectious organisms an excellent opportunity, and cystitis, with possible stone formation, may set in. After a varying long period this obstruction begins to tell on the ureters and on the kidneys. Hydroureters and nephroses develop and the parenchyma begins to suffer more and more as atrophic and fibrous changes take place in the kidneys. Infection once introduced into the bladder may ascend the relaxed ureters and the whole upper tract become infected.

*The Mechanism of Prostatic Obstruction.*—Every surgeon who has enucleated prostates by the suprapubic route has noted that the prostatic urethra instead of being obstructed in the sense of strictured is usually widely dilated. This apparent contradiction has interested me for a long time and led me to make a rather extensive study of the posterior urethra and neck of the bladder with the endoscopic methods to determine the mechanism of obstruction. In the great majority of cases the mechanism is the same. In a small minority, those cases where there are small submucous nodules in the posterior urethra, and those in which there is a typical ball-valve projection of the middle lobe without lateral lobe involvement, as well as those derived from the Albarran glands, effect the obstruction in a self-evident manner.

If one employs the close vision convex sheath cystoscope brought out by Wappler in 1911 with the catheterizing optic (which looks slightly forward) one can observe the play of the adenomatous lateral lobes of the prostate as distinctly as the laryngeal mirror shows the movements of the vocal chords. In such a picture one sees the lateral lobes projecting into the urethra as two symmetrical masses (usually) and extending down to a little beyond the bladder end of the verumontanum. With this in the field, if you ask the patient to breathe deeply, you will see the urethra open up as a more or less wide trough, as the lateral lobes move away from each other, and then if you ask the patient to strain or press you will see the lateral lobes crowded together and obliterating the urethra Under the increased intraabdominal pressure the prostatic adenoma is forced down in straining into the prostatic capsule, and the wide posterior urethra is compressed from side to side, thus producing obstruction to the outflow of urine. The ocular demonstration of this distinct play of the lateral masses is excellent proof of this *a priori* explanation of the nature of the obstructive process, and this explains the fact, so often observed in these cases, that the harder they strain the more difficult it is to empty the bladder.

*Mortality in Prostatic Adenoma.*—Only twenty-five years ago one of the leaders of the profession, Guyon, stated that the operation of the removal of the prostatic obstruction was a practical impossibility, and that even if it should occasionally succeed, the marked disturbances secondary to the original trouble would stand in the way of a complete cure of the patients so afflicted. Within a generation this all has changed and the incorrectness of both these postulates has been proven thousands of times.

During this period, especially in the last few years, reports of series of cases, have been made, in which the patients have been completely cured and in which the number that have succumbed has been rather low. Such reports do not, however, express the true state of affairs as applied to the general run of cases that one encounters in a hospital service in a city such as New York. Here our private cases come for relief much earlier than the charity cases, with the result that statistical reports on these two types of cases will show a marked difference in the end results. With an exaggeration of the low mortality following prostatectomy for adenoma, the medical man to whom the case first appeals is liable to put off consultation with the surgeon till the patient becomes a much poorer risk. This is very noticeable in this disease, which differs from most surgical conditions, in that its course is very slow, and consequently there seems to be no great urgency for radical measures. This procrastination will invariably lead to some harm, and instances of the fatal results following delays come to me with unfailing regularity. During the last two and a half years I have seen at least eleven cases of neglected prostatic adenomata that were sent in to the hospital for surgical relief when they were no longer fit surgical risks, and seven in a very few days went into uremic coma, despite active treatment, and died. This is liable to be the end result of every neglected prostatic obstruction case, unless measures are taken at the proper time to avoid such an outcome, provided the patient does not die of some intercurrent diseases. If such cases are operated upon, naturally they will die, and the excellent results that are so often reported would be materially changed.

If the indications for operative interference could be drawn as carefully as in most surgical conditions harmful delays would be less frequent.

*Indications for Operation.*—This to my mind is one of the most difficult propositions that we have to face. I believe the difficulty disappears in a measure if we divide our cases in accordance with their social status. A man who can afford to keep a trained attendant who can regularly empty his bladder and wash it out is in an altogether different position from one who has no such means at his control. Even the former is not free from all the risks incidental to such manipulations, but provided he is comfortable under such treatment he may prefer it to running any operative risks. His poorer fellow must, however, have recourse to an operation or go from bad to worse without any relief worthy of the name.

(1) Attacks of retention; (2) marked frequency

of urination, especially nocturnal frequency which prevents sleep; (3) bleeding; (4) painful and difficult urination; (5) chronic intractable cystitis, especially when accompanied by stone formation, are to my mind the clearest indications for surgical relief, provided a brief period has been devoted to such medical therapy as the use of Wildungen water (Georg Viktor Quelle), ergot, and rest, without avail. The future will have to decide whether radium and massive *x*-ray dosage will prove of any avail. Transurethral cauterization with the Bottini incisor, as well as with the high-frequency current, seem to have only temporary effects.

*Preliminary Study of Prostatic Cases.*—There is no type of cases where it is more important to make a preliminary study of the patient prior to running the risks incidental to an operation than cases of prostatic adenoma. The experienced clinician often has the ability to size up his patient before operation in a most satisfactory manner, but even he will find that occasionally he is surprised in a most remarkable manner.

There are three things in connection with every prostatic that I think should be studied: (1) The anatomical and functional condition of his urinary tract; (2) The condition of his heart; (3) The condition of his arterial system.

1. In my experience most prostatics can be cystoscoped, and I believe that this should be regularly done. Not only is this of value in confirming the diagnosis, but in view of the fact that adenoma of the prostate is at times associated with benign or malign papillomata of the bladder, these should be recognized and destroyed if possible before the prostate is attacked. Another advantage of this examination is to determine the presence of stones that may be packed away in diverticula, and which will be left *in situ* at the time of operation if they have not been recognized before. In one case at the cystoscopy, I was able to dislodge a number of stones thus packed away in different pouches in the trabeculated bladder, and then remove them prior to the prostatectomy. Catherterization of the ureters I believe is only rarely of advantage in these cases, and unless there is a very distinct suggestion that the supravesical organs are asymmetrically diseased, I do not try to do this. Further information is obtained by routine *x*-ray examinations of the whole urinary tract, which throws light on the presence or absence of calculi in the kidneys as well as often gives some idea of the position and size of these organs. This also calls attention to ureteral and, frequently, to vesical calculi.

Important information is obtained by an examination of the functional activity of the kidneys. I have made use of all the more popular tests, such as cryoscopy, phloridzin, indigo-carmine, experimental polyuria, phthalein, and believe they are of value in the determination of very bad risks, provided, as is usually the case, one can feel fairly sure that the supravesical condition is symmetrical, and that one kidney is not inhibiting the other, so as to make the combined function appear reduced. *It can be said with absolute truth, that the nearer a patient comes to a condition in which his excretion of these various substances is zero, provided his supravesical disturbance is symmetrical the greater the risk of any operative procedure, and those with zero excretion should not be operated upon until they have been treated preliminarily and their kidneys given a chance to improve.* The following cases are of unusual interest in this connection, and in view of these experiences I would not operate when the excretion is zero or practically zero, provided I feel fairly sure that the kidneys are not asymmetrically diseased and that an inhibitory influence is not making for the negativity of the tests. The urea excretion as seen in the following cases is of no great value in determining the functional value of the kidneys. Attempts at testing the function by throwing more urea into the circulation have not proven as yet of any marked value.

Case I.—H. S., 60 years old (history abbreviated); admitted February 12, 1912. For past year has had attacks of frequent micturition and burning on urination. Three weeks ago a number of calculi were removed from his bladder through the cystoscopic sheath in the dispensary. For the past two months the frequency and pain have become worse; voids every hour or half hour. Urine is turbid and has pain over bladder. General condition is good; well nourished. Heart sounds are feeble, chest is barrel shaped, pulse is regular, good force, increased tension, moderate arterial thickening. Prostate is enlarged by rectum, firm and hard. February 13, 1912.—Cystoscopy. Diffuse cystitis; base filled with many grayish white calculi, some of which are faceted, others broken; prostate enlarged; several small stones washed out through sheath. February 14.—Phthalein test. (I) No excretion; injection made at 12 noon, and up to 4:20 P. M. negative. February 15.—Phthalein test.. (II) No excretion; injection 10:55 A. M., and up to 1:20 P. M. no excretion. February 16.—Phthalein test. (III) 3:11 P. M. to 4:11 P. M. 4 ounces of urine secreted, but no excretion of coloring matter; 4:11 P. M. to 4:30 P. M., faintest excretion of phthalein (inestimable amount). Phloridzin test. Minims xv of a 1 per cent. solution in alcohol injected at 4:12 P. M.; up to 5:05 P. M., no reaction (solution tested on other normal patients produced glycosuria). Indigo-carmine test. Three drams of 0.4 per cent solution injected at 4:10 P. M. At 8 P. M. the first trace of a very feeble excretion appeared. Urea excretion. (24 hours' specimen), 1 per cent. concentration; total, 18.6 grams. Patient refused further treatment and went home against advice; readmitted May 10, 1912. He had felt well and fairly comfortable for one month after leaving the hospital; past two months feels worse again and has become incontinent; permanent catheter inserted. May 13.—Indigo-carmine test. (II) Four drams of the above solution injected at 10:50 A. M. At 2:30 P. M. urine began to show weak stain. Fundi are negative. May 15.—Phthalein test. (IV) Injection at 11:30 A. M. Negative up to 5:30 P. M. May 16—Phthalein test. (VI) Injection at 1 P. M. At 6 P. M. faintest reaction. Less than 5 per cent excreted. May 16.—About 100 stones removed from the bladder through the sheath of the cystoscope. With lithotrite some larger stones crushed and evacuated (Novocain anesthesia). Operation was brief and three separate instruments were introduced into the bladder, each only once, *i.e.* cystoscope, lithotrite, cystoscope. There was no injury and patient was not excited. May 17.—Patient is dull and quiet; distinctly uremic. Tongue is dry; vomited several times. May 20.—Under active treatment: Diuretin, rectal drip, colon irrigations, subcutaneous salines, etc.; patient improved. May 20.—Phthalein test. (VI) Injection at 11:45 A. M. First appearance of faintest reaction at 2 P. M. During the next 24 hours passed inestimable amount of the phthalein. May 22.—Without any local anesthesia many more stones rapidly evacuated from the bladder without any injury and without any distress to the patient. May 25.—Patient has been duller again; breathing labored; pulse weaker; passes less urine; placed on same treatment as before without avail. May 26.—Became more and more stuporous; breath urinous and died in uremia. Urine examinations showed large amount of pus and albumin with urea in the 24 hours' specimen; May 12, 0.9 per cent., 13.5 grams; May 13, 1.1 per cent., 17.6 grams. On forced nitrogenous diet: May 22, 1.2 per cent., 11 grams; May 23, 1.5 per cent., 19 grams. Autopsy: Prostatic adenoma with hypertrophied bladder; marked cystitis and a few vesical calculi; hydroureter and hydronephroses on both sides and atrophic contracted kidneys.

Case II.—D. G., 66 years old (history abbreviated); admitted November 13, 1913. Well till four years ago, when taken ill with gastric symptoms, pyrosis, eructa-

tions, vomiting; became costive; no headache nor visual disturbances; urinates four or five times each night. Since four weeks has become so weak that he went to bed; had retention of urine for which he had to be catheterized. Physical examination: General condition, fair; emaciated; tongue dry; heart sounds of fair force; second aortic accentuated; some general arteriosclerosis. Lungs show signs of a tubercular process in the right upper lobe. Prostate is enlarged by rectum; slight edema of the ankles; permanent catheter inserted and antiuremic therapy introduced; blood pressure, 130 mm.; residual urine 9 ounces. Test meal: Free HCl 30, total acid 50, lactic acid 0, blood (benzidin) 0. Blood examination: Hb 50 per cent.; RBC, 4,300,000; WBC, 20,800; polynuclears, 83 per cent.; lymphocytes, 14 per cent.; large mononuclears, 3 per cent. October 30.—Phthalein test. (I) Negative; no excretion in 24 hours. November 31.—Indigo-carmine test. (I) No excretion. November 1.—Phloridzin test. (I) minims xv of a 1 per cent. solution; no excretion in 12 hours. Nov. 3.—Eye examination shows slight changes in the retina often seen in chronic nephritis. November 3.—Phthalein test. (II) Very faint reaction at 3½ hours. November 4.—Indigo-carmine test. (II) No excretion in 24 hours. November 5.—Phloridzin test. (II) Very faintest reaction at 4 hours; Albarran polyuria test repeatedly negative. November 8.—Mental condition less clear and patient is weaker. November 11.—Phthalein test. (III) Faintest excretion in 4 hours. November 13.—Died. Urine in good amounts passed every day, containing slight trace of albumin and some pus cells with urea in the 24 hours' specimen: October 31, urea 1.6 per cent., 16.3 grams; November 4, urea 1 per cent., 16.5 grams; November 4, 1.2 per cent., 13 grams. Autopsy: Prostatic adenoma, chronic cystitis, hydroureter, and nephrosis on both sides, with extensive parenchymatous degeneration and interstitial nephritis.

2. The only method that gives us an idea as to the function of the heart is the observation of its activity under normal conditions and under stress. Congestive signs in the viscera, edema of the dependent parts of the body, feeble pulses, and marked acceleration of the heart's activity after exercises, naturally suggest to the surgeon great caution, as the risk of a fairly severe operation may be too great. If, however, none of these symptoms of disturbed function are in evidence, this system will not figure adversely in the sizing up of any particular case.

3. In many old men that come for relief the picture of an arterial marasmus dominates the whole picture. These patients have begun to undergo the process of shrinkage seen regularly in the very old. Their arteries seem to be unable to carry to the peripheral parts sufficient nutrition. Many of these look to the clinical surgical eye, as unjustifiable risks, but frequently on rest and forced feeding what at first blush looked like a bad risk, improves, takes on weight and becomes a subject that can stand the operation satisfactorily.

*One-Stage and Two-Stage Operations.*—Now despite all this preliminary work the surgeon may be in doubt as to his patient's ability to stand an operation, which occurs not infrequently. Provided the patient must not be relegated to the group of unjustifiable risks, (vide such cases as quoted above), I believe this group of cases should be operated upon in two stages, but only after they have had the advantages incidental to preparatory treatment of their bladder retention, etc. There can be no doubt that in the two-stage operation the patient has a better chance, and when in doubt I invariably operate in this way. At the first operation the bladder is quickly opened and a tube placed snugly within it, the wound in the soft parts and in the bladder being closed down to the tube, which is surrounded with gauze to the bladder incision. Depending upon how the patient stands this, the adenoma is enucleated at some later date. The bleeding at the time of the enucleation is less than at the one-stage operation, and the perivesical tissues are well protected by the reaction that followed the first stage. The total time consumed by the two operations is frequently shorter than that required by the operation in one stage, and the bed of the prostate gives less secondary bleeding. Moreover, the closure of the wound provided the tissues are drawn together at both stages, is not much slower than after the one-stage operation. On the other hand patients in excellent condition, I operate upon in one stage, provided they have no stones or severe cystitis. The only objections to the two-stage operation are that it takes somewhat longer to close the wound, and many patients object to what seems like two operations. These are not insuperable difficulties, and where the two-stage operation is indicated it should be done.

Of the 60 cases operated upon by our staff, 36 were looked upon as sufficiently good risks to warrant a one-stage operation whereas 24 were considered questionable risks and were operated upon in two stages. Of the former series two died and of the latter 3 ended fatally (5 per cent. and 12 per cent. mortality respectively).

*Technique of the One-Stage Operation.*—The bladder is opened by a 2-3 inch suprapubic median incision, after filling the viscus with air or fluid, the patient being placed in slight Trendelenburg posture to allow the peritoneal reflection to be more readily held out of the way. A finger is introduced through a small opening in the bladder and with counter pressure through the rectum with the operator's finger (left hand), the mucous membrane is broken through and the cleavage line, between the adenoma and the false capsule, made by compression of the adjacent prostatic tissue, is entered. It seems quite immaterial where this break in the mucous membrane is made. I believe it is more readily accomplished over the most prominent part of the growth, and I begin the attack at this spot. The enucleation of all the tumor is readily accomplished and then the enucleated mass or masses are delivered. This leaves a cavity whose walls and edges may bleed seriously. Hot packings introduced into this cavity and compression of this area for a few minutes between the rectal finger and a sponge holder which steadies the hot packing above will frequently stop most of the bleeding, so that no packing need be left in the bed of the prostate. Should such manipulations, as well as the use of hot saline irrigations, fail to control the bleeding a dry long gauze packing with a heavy silk thread attached, is firmly placed in the prostatic bed the thread reaching through the bladder and out through the large drainage tube. The bladder is sewed snugly about this and the wound closed in layers, being careful to attach the bladder to the rectus muscles and fascia by means of one catgut suture, below the tube, thus obliterating the approach to the prevesical space and at the same time bringing the bladder opening well above the posterior surface of the symphysis. Two small packings are placed above and below the tube down to the bladder wall to act as drains and to determine the flow of wound secretions toward the opening that has been left in the parietes.

*Anesthesia, Hemorrhage, Infection of the Prevesical Space.*—Ether preceded by gas has been used in the majority of cases. Occasionally gas and oxygen, and rarely local anesthesia for the pre-

liminary cystotomy. Pulmonary complications have been very exceptional. Pneumonia was once noted and occasionally was there a transient bronchitis. Gas followed by ether gave better relaxation and was in general preferred on that account.

There have been no cases of alarming bleeding, and it was not necessary to reopen the bladder and pack the bed or clamp bleeding vessels, in any case.

The prevesical space gave slight trouble in only one case and in this patient I tore through the neck of the bladder behind the symphysis in enucleating a very adherent large mass. This required drainage as I could not suture the thin wall of the bladder. A mild infection delayed the closure of the wound for several weeks. The patient, 83 years of age, made, however, an excellent recovery. But for this there have been no prevesical space infections.

*Mortality.*—In this series of 60 cases we lost 5 patients, a mortality of a little more than 8 per cent. Of these 5 deaths 2 followed the one-stage operation and 3 followed the two-stage procedure. The nature of these cases will be seen from the following:

Case I.—Had a sharp rise in temperature following a difficult cystoscopy for prostatic enlargement associated with calculi. Not suspecting that this might be of moment, I rather inadvisedly did a one-stage prostatectomy shortly thereafter. This patient developed anuria and subsequently pneumonia. For a time improved and seemed to be doing well, being out of bed and voiding portion of his urine. Five weeks after operation he died, having developed signs of renal involvement. Autopsy showed a bilateral suppurative condition in his kidneys and gangrenous condition of the pelves.

Case II.—Died five days after a one-stage operation of cardiac weakness. This patient, 72 years old, might have done better had a two-stage operation been done. After the operation we had great difficulty in moving his bowels, and the progressive distention embarrassed his heart action. Despite heroic measures we could not control the situation and the patient, who undoubtedly had a fatty heart, gradually became weaker and could not be relieved.

Case III.—Died four weeks after the second stage of a two-stage operation from an apoplectic stroke.

Case IV.—Died twelve days after the second stage from an embolism, having been up and about several days.

Case V.—Was a case of advanced myelogenous leucemia, with a spleen reaching into the suprapubic region. He died ten days after the second stage of what seemed to be some blood crisis, as his local condition gave us no reason for alarm.

As all five of these cases died in the hospital while still under our care they must be considered as the operative mortality, even though in the last three cases death is not so directly connected with the operative procedure as in the first and second cases.

*Post-Operative Care.*—By the one-stage technique outlined above we regularly keep all our one-stage patients absolutely dry until suprapubic tube drainage ceases. Those done in two stages usually leak after the second stage as the drainage tubes do not regularly fit the stretched bladder opening snugly. After 24 hours the fit becomes snugger and the patients are comparatively dry and comfortable. Caffeine and strychnine are used as stimulants, and as soon as the patients react they are sat up in bed and given saline in good quantity per rectum. If there has been considerable oozing the bladder is washed to expel clots, a catheter being introduced through the drainage tube which naturally is disconnected for this purpose. After about 3 or 4 days the packing in the bed of the prostate is carefully withdrawn through a Kelly endoscope which is introduced into the bladder threaded over the silk thread after withdrawing the large drainage tube. A very warm irrigation usually controls the bleeding caused by drawing out the packing, and then after thoroughly drying the edges of the wound a receptacle of hard rubber* is glued† over the drainage hole to collect the urine, and keep the patient dry. Whenever these do not functionate properly a large absorbent moss pad dressing is bandaged in place to take up the copious flow of urine. These cases are then irrigated carefully each day through the urethra with a urethral tip, using any mild antiseptic solution, with only sufficient pressure to get by the compressor urethral muscle. Occasionally a soft rubber catheter may have to be used for this purpose. The urine should be kept acid and urotropin administered. After 10 to 12 days of irrigating it is usually advisable to stop all such manipulations and allow the wound to close, if everything is ready for closure in the suprapubic wound. Under such circumstances, continued irrigations will reopen the closing fistula and delay the course of the case. It is possible in this way to get complete closure within 12 to 14 days without inconveniencing the patient by passing urethral instruments. The many fine points in the after treatment of these cases experience alone will teach. In a very recent paper by Marion he attempts to give in detail many of these, which are somewhat out of place in this sketchy paper.

*The end results of suprapubic enucleation of prostatic adenomata* are most ideal. The patients heal up most kindly and are completely restored to health. Their sexual functions are not interfered with and urination is perfectly normal in almost every case. The cystitis that regularly follows the opening of the bladder, as well as that which exists so often prior to operation, improves rapidly after the removal of the obstruction to the outflow and within 6 to 10 weeks the patient's urine is nearly clear or absolutely so. Incontinence is most unusual after this operation, and the only symptom that may remind the patient of his previous trouble is the persistence of some frequency. In the majority of cases the control is perfect, and according to the work of A. Hyman the compressor group of muscle fibers is responsible for this in most of these cases. The fact that the sphincter at the bladder's neck does not functionate in many of these cases is evidenced by the oft-repeated remark that patients make, concerning the absence of the ejaculation during intercourse and the voiding of their semen in the first urination thereafter, mixed with the urine.

A Case of Nystagmus.—H. Campbell reports a case of this condition in a man, aged 36, who for two years has suffered from lateral nystagmus on turning the eyes to the right. The nystagmus is accompanied by giddiness and widespread nervous perturbation. The trouble incommodes him in his work as shop assistant, especially when taking down articles from shelves. Turning the head to the right while the eyes are directed forwards does not cause nystagmus. Turning the eyes to the right with closed lids causes nystagmus with little, if any, giddiness. He has had some dull occipital headache. Beyond the nystagmus and a moderate defect of hearing no abnormal nervous condition can be discovered objectively.—*Proceedings of the Royal Society of Medicine.*

# A REPORT OF TEN CASES OF ACUTE PERFORATING GASTRIC AND DUODENAL ULCER.*

By V. F. MARSHALL, B.S., M.D.,
APPLETON, WISCONSIN.
ATTENDING SURGEON ST. ELIZABETH HOSPITAL.

ACCORDING to Musser, the perforation in gastric and duodenal ulcer occurred in 28.1 per cent. of a series of 1,800 cases. This condition therefore is more frequent than was thought to be. Perforations occur in patients at all ages. They are more frequent during the ages of 30 and 40 years and much more common in men than women. Acute ulcers perforate more frequently near the cardiac end of the stomach, while chronic ulcers perforate near the pylorus. They are more frequent upon the anterior wall, both in the stomach and duodenum. They occur infrequently upon the lesser curvature and almost never upon the greater curvature. It is said duodenal ulcer perforation is more frequent than that of gastric ulcer. Attention is called to this condition by its sudden onset with the classical symptoms of pain and rigidity of the abdominal muscles and the history of a previous gastric indigestion. The pain is excruciating and usually is confined to the upper abdomen. Patients suffering with perforation are as a rule found lying upon their back with the thighs flexed and a pronounced boardlike rigidity of the muscles. The breathing is therefore thoracic. Eliot states that the point of maximum intensity of the muscular resistance is a valuable guide to the site of the lesion. The patient's facial expression is most anxious and points to some intraabdominal catastrophe. Tenderness is present at once after perforation and at first is located at the site of perforation—later with the spread of peritonitis it becomes more diffuse. In the later stages this sign makes the differential diagnosis more difficult. The fluid from perforation first fills the right kidney pouch, then descends along the outer side of the ascending colon to the right iliac region and the pelvis. For this reason this condition may be confused with perforative appendicitis more than any other lesion. Shock may or may not be present and is purely a personal factor. Nausea and vomiting are usually present although not always constant. It is said to occur more frequently in duodenal than in gastric perforation. Blood is usually absent in the vomitus but when present it is of great assistance in the diagnosis. Temperature and pulse are but slightly affected in the early hours. Later both are materially increased. Again both temperature and pulse rate in the early hours are affected out of proportion to the pathology present and like appendicitis are personal factors.

There is but one rational treatment to be instituted in perforated gastric or duodenal ulcer, which is operative, and this should be instituted at once. Upon opening the abdomen one of the following procedures should be done. (1) The ulcer, if favorably located, may be excised and the walls then restored by suture. If located at the pylorus a pyloroplasty may be done. (2) Or simple inversion by a purse string suture which may be reinforced by a second purse string or interrupted sutures. (3) Drainage is always necessary in all cases for the contents may not be sterile. (4) Gastroenterostomy is not necessary unless the lumen is seriously interfered with so that the passage of food is obstructed. However, gastroenterostomy is to be advised for its beneficial influence upon ulcer, but great judgment must be exercised in its application for it prolongs the operation and in some hands this procedure combined with the closure of the ulcer would only add to the mortality.

The following cases occurred in the writer's experience. The series comprises ten cases of which six were gastric and four were duodenal perforation.

CASE I.—My first case of acute perforated gastric ulcer was as follows: Miss G. B.; age 17; October 10, 1906. Her illness began very suddenly four days previously. There was no history of previous stomach disturbance. A physician was called the first day of her illness, who administered some opiates. Her condition did not improve, but became gradually worse, and I was called the fourth day and found her with all the clinical manifestations of a generalized peritonitis. The history was indefinite as to whether it was of appendiceal origin. Consent was obtained to institute drainage, which was done under gas and oxygen anesthesia. The patient succumbed eight hours later. Upon postmortem the appendix was normal, but a perforation of a gastric ulcer upon the anterior side was found to be the cause of the peritonitis.

CASE II.—Mr. R. V. M.; age 26; November 27, 1910; clerk. Symptoms of indigestion for three or four years; had to be be very careful as to his diet. Pain an hour and a half to two hours after eating. While at work about 10 A. M. was taken with severe pain in upper abdominal region. Seen six hours later. Diagnosis of acute perforated duodenal ulcer made, and operation advised and accepted. Through right rectus incision, perforation sutured; drainage; recovery. Some symptoms of impaired gastric digestion persisted for more than a year, which finally disappeared.

CASE III.—Mrs. E. M.; age 24; December 21, 1910. Seen at 8 A. M.; symptoms of stomach trouble for more than two years. Had frequent eructations of acid fluid after eating; occasionally pain half an hour after meals. Fried foods caused great distress. Was taken suddenly with pain in mid portion of abdomen about midnight; some nausea and emesis. Was seen by another physician who diagnosed appendicitis and advised operation. Upon examination the abdominal muscles were generally rigid, with most tenderness over McBurney's point. The symptoms were not altogether positive of an appendicitis; operation was advised and accepted. Through a gridiron incision the appendix was exposed; this was small and not inflamed. The appendix was removed. Much exudative fluid of a yellow color flowed out, which pointed to the perforation of an ulcer of the stomach or duodenum. The primary wound was closed. A right rectus incision was now made and a perforation found on the anterior side of the stomach at the pylorus. The ulcer was excised and a pyloroplasty done. Tube drainage was inserted. Recovery was uneventful and there have been no symptoms since.

CASE IV.—Mr. L. B.; age 23; school teacher, Dale, Wis. Referred by Dr. Johnson, May 28, 1911. Was occasionally troubled with so-called indigestion which was attributed to some carelessness in diet. The day previous assisted his father in farm work and felt very well. Was attacked with sudden severe pain in upper portion of abdomen in early morning. The pain was excruciating. Dr. Johnson was called; an opiate was administered. I was called by telephone about 8 o'clock A. M. and told of this condition and advised his immediate removal to the hospital, the symptoms pointing to an acute perforation of some one of the digestive organs. Upon his arrival at the hospital (the trip having been made in an automobile) he was immediately taken to the operating room and a right rectus incision made. A perforated gastric ulcer was found about an inch or little more to the left of the pylorus upon the anterior side. The perforation was sutured with a circular suture and the omentum tacked over. The appendix was also removed. Tube drainage was instituted; recovery uneventful. At present he is located in Atlanta, Ga., as auditor for one of the Southern railways and enjoys good health.

CASE V.—Mrs. F.; age 42; Clintonville, Wis.; referred by Dr. Finney, October 19, 1911. For three years past has had much trouble with stomach. Fre-

*Read at the Fox River Valley Medical Society, Menominee, Mich., October 22, 1913.

quent acid eructations and pyrosis. Pain half an hour after meals and located over epigastric region. She entered hospital for examination and diagnosis. A test meal showed a total acidity of 90, both the free hydrochloric and combined acids being greatly increased. A diagnosis of ulcer was made and inasmuch as medical treatment of two years had been ineffective an operation was advised. This was to be done the following morning. About 3 A. M. patient complained of a very severe pain in the upper portion of the abdomen. She endeavored to vomit, but could not do so. The hospital called me and an opiate was advised to be given at once. As she was prepared for operation, the delay of three or four hours upon an empty stomach could cause no material harm. Through a right rectus incision an ulcer of the pylorus was found with a pin point perforation. This was sutured and a posterior gastroenterostomy performed; no drainage. The recovery was uneventful. February 17, 1912, the patient returned on account of a spasmodic pain due to a "pulling," as she described it, in the upper abdomen. The distress made the patient very uncomfortable, so another incision was made, and adhesions found which united the right side of the stomach to the abdominal wall. There were also some adhesions upon the left side of the stomach and abdominal wall. These adhesions were divided and sutured over. The gastroenterostomatic opening was found to be in excellent condition. The old scar was excised. The patient had also gained materially in weight. January 21, 1913, the patient returned, stating she was now feeling quite well and wished to have the gastroenterostomatic opening closed. This was done the next day, when she again made an excellent recovery. Recent inquiry was made as to her present condition, and she advised us she was now enjoying good health and had gained materially in weight.

Case VI.—E. W., laborer; age 24; March 29, 1913; referred by Dr. Reinick. Two years ago had an appendectomy performed. At this time had suffered with gastric distress and some pain after meals. Above symptoms had never entirely disappeared following the operation. Occasionally suffered with acute exacerbation of pain in the epigastrium. Patient reported for work as usual that day, but toward noon suffered with more pain in the upper abdominal region. He ceased work at noon and returned to his room. The pain became very severe in the afternoon, when he called Dr. Reinick. I was requested to see the patient, which I did about 8 o'clock in the evening. A diagnosis of perforated ulcer was made and he was sent to the hospital for a laparotomy. Upon opening the abdomen a perforated duodenal ulcer was found which was closed with two purse-string sutures; drainage to the subhepatic space. His recovery was uneventful.

Case VII.—Mr. A. C., farmer; age 49; May 10, 1913; referred by Dr. Greenwood. For a year had been suffering more or less with stomach trouble. Had been more or less of a heavy drinker of alcoholics for some years. Had lost 10 to 15 pounds in weight. The week previous to his operation had quite severe pain in the epigastrium, acid eructations, and constipation. Was taken with sudden acute pain about 6 o'clock in the morning. He vomited a small quantity of fluid, which contained blood. His physician was called and saw him about 8 o'clock. Morphine was administered to allay the pain. His symptoms and physical appearance pointing to some intraabdominal lesion, I was called to see the patient in consultation with Dr. Greenwood and was told to come prepared to operate. A diagnosis was made of perforation of an ulcer of the stomach. Upon opening the abdomen a pin point perforation of an ulcer upon the anterior side of the stomach adioining the pylorus was found. This was closed and invaginated with purse-string sutures. The patient took his anesthetic very badly and we had to give enormous quantities of chloroform to relax the abdominal muscles. A gastroenterostomy with the oblong Murphy button was hurriedly made. A small drainage tube was inserted. Convalescence became established with normal pulse and temperature. The button was passed the elghth day. The patient was up and out of bed the tenth day. The twelfth day symptoms of a left sided lobar pneumonia developed, to which he succumbed two days later.

Case VIII.—G. K., Greek; age 32; proprietor of billiard and pool hall and bootblack stand; August 3, 1913. In this case it was exceedingly difficult to obtain a satisfactory history until late in his convalescence and then the facts were obtained only in fragments. Five years ago was greatly troubled with indigestion. This condition continued for about two years. Appetite was impaired and the ingestion of food caused pain about thirty minutes to an hour after taking it. Bloated after eating and had frequent eructations of a sour fluid. After this his condition improved so that the succeeding years he had practically no discomfort. A month preceding his operation he noticed that his appetite was not so good and that he was constipated. He consulted me about 12 o'clock Sunday, August 3. It was difficult to understand him, as he could not speak English very fluently. He requested something for his bowels as they had not moved for a week. He said his appetite was not very good and he had some general abdominal discomfort, but no pain. I gave him a prescription for two ounces of castor oil, which he took in some whiskey at the drug store. I left my office for home and just arrived when a telephone message came from his partner informing me that the patient was in great pain. Upon my arrival he was found to be suffering intensely—a boardlike rigidity of the abdominal muscles and a general condition of shock. A diagnosis of perforation of either a gastric or duodenal ulcer was made and he was advised to go to the hospital at once for operation. Upon opening the abdomen the odor of whiskey was noticeable and the appearance of oil came to view so that the diagnosis of a perforated ulcer was verified. A perforated ulcer of the duodenum was found. This was closed with two purse-string sutures and a piece of the omentum was tacked over. Drainage was instituted. His convalescence was uninterrupted and he enjoys at present apparent good health.

Case IX.—Mrs. G.; age 50; Hayton, Wis.; referred by Dr. Bolton, Chilton, Wis.; August 25, 1913. For more than two years has suffered with pain and distress about one hour after eating; appetite greatly impaired. The stomach disturbance had been greatly increased the preceding four or five weeks, so that the patient had only partaken of broths, gruels, and toast. The patient retired at night as usual, having no more than the usual digestive distress. During the early morning hours, about 4 or 5 o'clock, pain became very intense in the hepatic and epigastric region. Some nausea, but no emesis. Dr. Bolton was called and administered some sedatives. The abdominal muscles became very rigid. As her condition did not improve and the symptoms were unlike any others he had met with, he asked for consultation. I was called by Dr. Bolton at noon and advised of her condition. A tentative diagnosis of perforation was made, operation advised, and a hurried trip by auto of thirty-five miles was made to her home in the country. Upon examination she presented all the symptoms of a serious intraabdominal lesion. The temperature was 100.2°; the pulse 130. An immediate laparotomy was performed and a perforated ulcer of the duodenum was found near the pylorus. A second ulcer, about an inch and a quarter, was found to the right. This was not perforated. The first ulcer was sutured by two purse-string sutures and an omental flap tacked over. Drainage was instituted. As the patient's condition was very grave, it was not deemed advisable to do a gastroenterostomy. The patient did very well the succeeding days, the tube being removed the fifth day. Near noon of the sixth day, August 31, the nurse noticed a discharge of fluid shortly after swallowing. I was again called by telephone while at Winneconne and apprised of her condition, and made a diagnosis of a perforation of the second ulcer. Another trip by auto was made, the distance this time being sixty miles. When we arrived at the patient's beside, about 9 P. M., her condition was extremely critical. The temperature was 101°; the pulse 140 and very irregular and intermittent. Preparations were made again for an immediate reopening of the original wound, and there were grave doubts as to whether the patient would survive the ordeal. The perforation was found of the second ulcer. Closure was made as in the case of the first ulcer. The work was difficult, and if it had not been for the help of a "trouble" electric hand light we would not have accomplished the closure. The patient was returned to bed none the worse for her experience. Her convalescence for the succeeding four or five days was stormy, but she finally weathered it and progressed on to a satisfactory recovery. This patient was seen four weeks later while in her neighborhood, and she was found to be looking well and expressed herself as feeling better than she had for some years. Gastroenterostomy was very much out of question in the first and decidedly so in the second perforation, but the patient was told that this procedure might have to be

done some time later in the event of any gastric symptoms arising.

Case X.—Mr. M. B.; age 35; fruit dealer; September 18, 1913. This patient presented himself at my office the afternoon of the day previous to his operation, with a history of stomach disturbance extending over a period of three years. Frequent acid eructations and pyrosis. Some nausea after meals and constipation. Pain half an hour after eating. For four weeks previous to his operation had to exert great care as to his diet, living principally upon gruels, milk, and eggs. For a week had had more tenderness than usual in the epigastrium. He had eaten nothing that day. The afternoon of his visit to my office he felt worse than usual and more pain in the epigastrium. The abdominal muscles were very rigid. He was sensitive, so that palpation was exceedingly difficult and unsatisfactory. However, with the history and physical findings a diagnosis of gastric ulcer which had penetrated the walls of the stomach to the peritoneal covering was made and immediate operation advised. This was accepted and he was at once sent to the hospital. Through a right rectus incision an ulcer was found an inch to the left of the pylorus, which had perforated and which was "plugged" with omentum. The ulcer was closed with purse-string sutures, and a gastroenterostomy and plication of the duodenum done. The appendix was removed; no drainage. The convalescence was uninterrupted. The patient left the hospital after two weeks. A visit from the patient October 14; he informed me he was now "feeling fine."

## SOME IMPORTANT FACTORS IN THE CONSERVATION OF HEARING.*

By C. M. HARRIS, M.D.,

JOHNSTOWN, PA.

OPHTHALMOLOGIST AND OTOLOGIST TO CONEMAUGH VALLEY MEMORIAL HOSPITAL, JOHNSTOWN, PA.

As this is a period in which eugenics is being persistently discussed, one might well argue that the attainment and preservation of good hearing depend to some extent upon one's ancestors, when we consider the claim that otosclerosis (an internal ear disease) is often hereditary; and also the less demonstrable manifestations in a person whose progenitors have been subject to lymphatic derangements of the respiratory tract, adenoids, tonsillar disease, etc. Anatomical anomalies, climate, methods of living, general diseases such as arteriosclerosis, the excessive use of alcohol and tobacco, to say nothing of the occupational influences, might have their effect sooner or later by transmission, if only by inducing susceptibility. In this connection one would do well to follow the advice of the humorist and wisely choose one's forebears. As most of our patients display more interest in the ills of the present or near future, the more practical hearing of this subject—its application to living patients—will receive most attention in this paper.

Diseases of the ear may be roughly divided into three classes: those affecting the parts concerned in the conduction of sound, those affecting the perceptive mechanism, and those acting on both. The external ear, external auditory canal, membrana-tympani, Eustachian tube, middle ear with its contained ossicles and attachments, and the cells found in the mastoid process, are all of service in the conduction of sound from the outer atmosphere. Lesions in any one or more of these parts deserve attention on account of the primary or secondary effect they may have on hearing.

Sound waves are collected by the external ear, pass through the canal to the membrana tympani, causing it to vibrate. These vibrations are then carried by means of the ossicles to the membrane filling in the oval window which transmits them to the fluids and nerve endings of the internal ear.

Malformations, or injuries of the external ear or canal should if possible be corrected with little delay. Plastic surgery may correct a deformed or injured auricle and even atresia of the bony canal. Tumors and inflammations deserve attention. Impaction of cerumen and the presence of foreign bodies are important on account, not only of obstruction and disordered hearing, but of the local irritation and even ulceration which may ensue, the membrana tympani frequently suffering injuries. Eczema of the canal may be caused by otorrhea, but in some instances no local cause is apparent. Scratching the parts with objects like toothpicks and hairpins can only do harm. Early treatment can accomplish much in relieving this irritating affection.

The membrana tympani is sometimes the subject of direct violence by penetrating objects and may be ruptured by the impact of air produced by explosions, the slap of a hand, etc. The practice of boxing ears should be condemned on this account. Careful aseptic treatment after such an occurrence will promote healing and prevent infection of the middle ear. The ossicles and internal ear may also share in injuries to the membrana tympani.

In considering the diseases of the middle ear one is justified in saying that nearly all of them originate in the nose and throat; and further, anything which prevents proper physiological breathing is very apt to be a contributing cause. Ciliated membrane containing mucous glands lines the nose, the Eustachian tube, and anterior part of the middle ear. From that point to the limits of the mastoid cells, the mucous glands are absent; in this respect resembling the lining of the accessory sinuses of the nose which is virtually an endosteum. This may explain the vulnerability of the mastoid to infection.

In my experience I have usually found chronic rhinitis in its varied forms to be secondary to diseased faucial or pharyngeal tonsils, sinus disease, and exostoses and deviations of the septum. Disordered turbinates are often only symptomatic. Obstructive tonsils not only cause poor nasal breathing, but tend to perpetuate it through mouth breathing. When the mouth hangs open, muscular action is not such as to cause the oral and nasal bones to spread, which produces a narrow face with corresponding nasal fossæ and a deflected septum. Obstructive elements of any consequence affect proper breathing and while one impaired breath counts for little, many may count for much. The vascular control in the mucous membranes becomes affected, and this in a short time brings about derangement of the mucous secretion associated with swelling. Finally the so-called catarrhal inflammation becomes demonstrable with its various objective and subjective symptoms. When the nasopharyngeal membrane becomes disordered as described, pathogenic germs, which we always have with us, find an inviting field, and successive attacks of acute rhinitis occur, adding fuel to the chronic process. It can well be claimed that colds occur only when our nasal membranes are non-resistant, be it due to local or general causes. The Eustachian tube is virtually a part of the nasopharynx and is commonly involved when the previously described acute or chronic inflammatory lesions are present. This tube is but 1½ inches long and its sides are almost

*Read before the Cambria County Medical Society, August 14, 1913.

in contact at one point. Instead of the middle-ear being normally ventilated with consequent suitable adjustment of the vibrating structures, a partial vacuum is created by the tubal obstruction, thus deranging the function of the entire ear.

It should be emphasized that a diseased faucial or pharyngeal tonsil, with or without the nasal changes to which I have alluded, frequently causes much chronic inflammatory change in the middle ear and tube, especially when adenoid tissue partly surrounds the tubal orifice.

Acute non-purulent tubotympanic inflammation is very apt to complicate the ordinary cold, the symptoms being diminished hearing, a swollen stuffy feeling about the tubes and ears, possibly associated with tinnitus or slight pain. Such a process often becomes subacute, lasting for several weeks. Local and general treatment is of great importance as each attack does some damage and may be one of the stepping stones to chronic deafness. Successive attacks should lead us to seek some local or general cause. In chronic non-purulent tubotympanic disease hypertrophy, atrophy, calcification of the soft parts with ankylosis of the ossicles may occur, and owing to the inaccessibility of the parts thorough success in treatment is unknown. I have already indicated the importance of intelligent nasal and pharyngeal surgery in the prevention and cure of ear disease. The term surgery is here used, as some corrective operation should not uncommonly precede local or general treatment. While I have nothing but commendation for the well performed tonsil and adenoid operation in properly selected cases, I feel free to predict that within a few years otologists will be confronted with some more or less obscure and irremediable tubal disorders directly due to impaired action of the tensor palati and levator palati muscles which normally dilate and contract the tube in addition to aiding in speaking, swallowing, and breathing, through their insertion in the velum palati. Reckless and inefficient operating, which is all too common, brings about actual muscular destruction, cicatrices, and contractures which are bound to affect physiological action. If every operator would take the trouble to study the fauces and pharyngeal vault of such cases subsequent to operation he would frequently find conditions worthy of criticism, even though the operation had been well done.

After permanent changes in the middle ear structures have taken place, the arrest of deafness, not cure, should be discussed with the patient. Many patients seek the aurist too late and his reputation suffers thereby. The primary causes in such cases should have received attention before the deafness became so plainly manifest. Therefore I repeat that all nasopharyngeal and aural symptoms should receive early attention if impaired hearing is to be prevented. In many instances deafness begins in childhood and becomes grossly manifest years after, when cure is hard to obtain. In adolescents or adults atrophic diseased tonsils, residual adenoids, septal and turbinal anomalies, sinus disease, and chronic rhinitis in some form are the things which separately or together frequently complicate aural disease. Nasal hyperemia can even affect the internal ear through a common venous outlet and tinnitus in such cases has been cured by relieving nasal stasis. Having surgically corrected any nasopharyngeal lesions in chronic catarrhal tubotympanic disease, topical treatment with inflation of the middle ear (preferably by catheter) is indicated as long as improvement is evident or on recurrence of symptoms. The many and varied uncertain lines of therapy will not here be enumerated. It should be stated, however, that prognosis and ultimate treatment depend upon local examination, tuning fork and quantitative tests, both before and after a few trial treatments. Climate has its good and bad effects. What seems good for one is not suitable for another. However, a bland equable climate neither too dry or too wet would seem desirable.

Next to the prophylaxis connected with the nasopharynx, judgment and care in the treatment of acute purulent otitis media and its complications are the most important matters in the conservation of hearing. Neglect of preventive nasal measures during fevers, especially the exanthemata, has caused many an abscess. Expectant treatment carried beyond the time for incision of the tympanic membrane has brought about much suffering, loss of hearing, and even death. In infection of the middle ear, the mastoid antrum and cells are to some extent bound to share in the process as they are but extensions of the cavity and the outcome will depend upon resistance, drainage, or both. In this disorder the greatest surgical sin consists in neglecting to make an early incision in the tympanic membrane. Protracted pain, fever, and deafness with visible changes in the membrane give ample basis for such an operation. Practically no untoward results follow an aseptic, extensive well-placed incision, while no estimate can be made of the troubles which may follow a delay; the same may be said of operative mastoiditis when the diagnosis has been well made. Chronic otorrhea frequently means diseased bone in the tympanum or mastoid and early drainage by tympanic incision will in most cases prevent it. Intelligent general and local after-care is, of course, a requisite.

It has been reported that nearly 25 per cent. of the patients attending aural clinics are children under 14 years of age; of this number, 50 per cent. are subjects of suppurative inflammation of the middle ear, and of this portion 10 per cent. or more owe their origin to the exanthemata of childhood. Of the cases of deafness in the United States 27 per per cent. are said to be due to suppurative middle ear disease of childhood. After excluding measles and scarlatina, it has been estimated that 95 per cent. of all discharging ears in children are due to adenoids and in the fevers mentionad adenoids are usually predisposing causes.

Chronic otorrhea is often neglected beyond prescribing a wash; if such therapy is not successful the otologist through his familiarity with the parts can not uncommonly cure it. Exuberant tympanic granulations, polypi, or even diseased bone may be removed through a perforation, causing the discharge to cease. That the nasopharynx should receive attention goes without saying. Diseased bone in the tympanum or mastoid may justifiably demand a tympanomastoid operation. The resulting common cavity can be treated through the external canal and finally becomes lined with epidermis. If such an operation is wisely chosen it is of great value. The recent operation of closing the tympanic end of the Eustachian tube to prevent chronic infection from the pharynx has its adherents and is no doubt of value.

The best protected and most essential part of the organ of hearing, the internal ear, may suffer indirectly from affections of the other aural parts

such as extension of acute infection, chronic inflammation, or injuries; directly from rarefying osteitis, systemic diseases, and the toxic action of drugs. Tobacco likewise causes changes in the auditory nerve. Syphilis, alcohol, tuberculosis, and the anemias are prone to cause nerve involvement. Abscess, embolism, or apoplexy in the labyrinth may cause immediate deafness and temporarily destroy our power of balancing, vertigo and vomiting being associated symptoms. An occupation connected with loud sounds should be avoided as it sooner or later adversely affects the nervous mechanism of the internal ear. After having briefly referred to the more important factors which influence hearing, I will attempt to justify the title of this paper by stating that skillful attention early in the course of most of these affections would, as intimated, do much to conserve hearing. Many patients come to us too late, whereas a large majority could have been benefited and the disease arrested had they come before the development of permanent damage. Contributing causes should be treated early and deafness, which is only a symptom, avoided. As much depends upon the actions of the patient as on those of the doctor. Cordial cooperation is necessary. Diet, hygiene, sanitation, personal habits, occupation, climate, and general health all have a vital direct or indirect bearing.

604 Johnstown Trust Bldg.

## FIVE HUNDRED EXAMINATIONS OF THE NOSE AND THROAT IN AN INSTITUTION FOR DELINQUENT BOYS.

By MAX TOEPLITZ, M.D.,

NEW YORK.

Reformatory institutions for children were founded in New York for the purpose of removing these from evil environment and of placing them under wholesome influences for the correction of immoral and criminal tendencies. The Hawthorne School, the first Reformatory for Jewish boys, received the first boy on April 25, 1907, and had under its supervision at the end of 1912 316 boys of from 8 to 16 years of age. The grounds of the Hawthorne School comprise 260 acres of meadows, orchards, and woodland at an elevation of 500 feet above sea level. The boys are distributed in eleven separate cottages, each of which houses 30 boys under the most hygienic conditions.

After their commitment to the Hawthorne School by the Judge of the Juvenile Court, the boys are examined with special reference to eye, ear, nose, and throat, as well as to their general condition, and are also vaccinated. In addition to this preliminary examination the boys, according to the rule of the Board of Estimate and Apportionment, are examined twice a year. The special care of the ear, nose, and throat has been entrusted to me. Here I have paid particular attention to the most prevalent affections: adenoids and hypertrophied tonsils. (Other conditions, such as septal deviations, nasal hypertrophies and purulent otitides are, since comparatively rare, included among the miscellaneous cases.)

The following table presents the examinations arranged in five groups of a hundred boys each:

The first group of 100 boys contained 70 diseased cases—enlarged tonsils (21), adenoids (23), and the two conditions combined (8). Of these 52 cases, 50 required and 25 demanded an operation, but only in one case were the tonsils removed; there were 30 normal and 18 miscellaneous cases in this group. Owing to the custom, then prevalent at the institution, of waiting for the consent of the parents, who in most cases are in ignorance of the benefit to their children, out of 50 operations needed only one could be performed. Another system was then adopted, under which, while the parents are notified of the intention to operate, their consent is not awaited. The operation is performed, unless they are heard from to the contrary prior to a certain date. The second group contained 75 diseased cases: adenoids (26), enlarged tonsils (18), and their combinations (21); 10 miscellaneous and 25 normal ones; 23 of the 65 requiring operation received it, 5 had refused it. In the third group the number of operative cases: enlarged tonsils (29), adenoids (13), and combined cases (31); increased to 73, of which 26 were operated upon; 27 were normal.

| | First 100 Boys 1910 | Second 100 Boys, 1911 | Third 100 Boys, 1911 | Fourth 100 Boys, 1911 | Fifth 100 Boys, 1911 and 1912 | |
|---|---|---|---|---|---|---|
| Enlarged tonsils | 21 | 18 | 29 | 19 | 19 | 106 |
| Adenoids | 23 | 26 | 13 | 9 | 18 | 89 |
| Adenoids and enlarged tonsils | 8 | 21 | 31 | 32 | 24 | 116 |
| Miscellaneous | 18 | 10 | .. | 2 | 10 | 40 |
| Entirely normal | 30 | 25 | 27 | 38 | 29 | 149 |
| | 100 | 100 | 100 | 100 | 100 | 500 |
| Operations needed | 50 | 65 | 73 | 59 | 45 | 292 |
| Operations performed | 1 | 23 | 26 | .. | 25 | 75 |
| Operations refused | .. | 3 | 5 | 9 | 6 | 23 |

The large percentage of cases requiring operation, 178 among 300, or 59⅓ per cent., evoked quite some criticism. It was, therefore, tried to eliminate the moderate cases of adenoids and enlarged tonsils, with the result that the fourth group contained 62 affected cases: enlarged tonsils (19), adenoids (9), and combined cases (32), 59 of which required operation; 38 were normal. In the fifth group were 71 diseased cases: enlarged tonsils (19), adenoids (18), and their combinations (24), 45 of which needed an operation.

In summing up all 500 examinations, 351 cases were diseased, of which 106, or 21⅕ per cent., had enlarged tonsils; 89, or 17⅘ per cent., adenoids; and 116, or 23⅕ per cent., were combined cases, and of these 292, or 58⅖ per cent., required operation, 23 refused it, and 74 were operated upon; 149, nearly 30 per cent., were normal. There were different degrees in size and disease of adenoids; different forms, diffuse and lumpy; different consistencies, soft and hard. The faucial tonsils also showed differences in size and consistency.

An argument arose that too many operations were required, and it was suggested to leave the diffuse, flat, and soft adenoids, and the small faucial tonsils untouched, and to remove only the large lumpy, hard growths. The diffuse, which appear smaller, are spread over larger surfaces and are usually more diseased than the large hard tumors. It is necessary to remove either all the diseased conditions or none at all. The figures of the year 1912 clearly elucidate this point; for among the 169 first examinations there were 25 cases of adenoids, 29 cases of enlarged tonsils, and 39 cases of enlarged tonsils and adenoids, a total of 93, or 55.03 per cent.; among these 93 thus affected there were 28 moderately affected, 65 requiring operation, 19 refusing operation, and 34 radically operated upon; of

the remaining 76 boys 41 were normal and 35 were miscellaneous cases.

In 1910 40 per cent. of all the 111 cases treated by the physician to the institution were traceable as to their origin to faulty conditions of the nose and throat, and all cases reported by the surgeon dealt exclusively with conditions of the neck.

MEDICAL WORK IN 1910 TRACEABLE TO NOSE AND THROAT

| Asthma | 1 |
| | 19 |

In 1911 18.6 per cent. of 102 cases treated by the physician were thus traceable to the nose and throat.

The operations for the removal of adenoids and enlarged tonsils were all performed in the hospital of the institution; all were radical, *viz.*, the tonsils were enucleated and every vestige of adenoids was eradicated. An anesthetic was administered only in a few obstreperous cases. In three cardiac cases the operation was abandoned; in one cardiac case an extreme hemorrhage took place after the operation, which was performed in ignorance of the cardiac condition. All operations effected thorough cures, and no recurrence took place in any case.

The Girard College of Philadelphia is the only other institution in the United States besides the Hawthorne School at which throat operations have been performed on a large scale. Among 1,500 boys of from 7 to 17 years of age tonsil and adenoid operations were advised in 152 cases; hypertrophy of tonsils was under observation in 124 cases; operations for deformities of septum advised in 25 cases; catarrhal and inflammatory conditions were recommended for treatment in 89 cases; 125 operations for the removal of tonsils were performed under general anesthesia by Dr. Joseph S. Gibb.

The school examinations of the Board of Health of New York show 15 per cent. of all the children with adenoids and enlarged tonsils, but these examinations are not done by expert laryngologists, the diagnosis is made by mere inspection of the mouth and not by mirror or finger; thus a large amount of cases of adenoids are overlooked. In this connection it is interesting to find that among 800,000 school children in Holland which were *suspected* of being affected with adenoids—the mouthbreathers and backward children only being suspected—6 per cent. was the result of this suspicion. The low percentage remains unaltered, where "dead speech," nasal speech, or conjectures are used to establish the diagnosis. With the aid of the finger, however, Strandhygaard[1] finds among 568 village school children 83 per cent., and Wilbert finds among 375 public school children 62 per cent. with adenoids, employing anterior and posterior rhinoscopy, when palpation was not permitted. Kafeman[2] finds among 905 boys 34 per cent., among 927 girls 39.2 per cent. of adenoids.

The delinquent boys are in the majority not strong and healthy, as their home surroundings and conditions help to undermine their constitution. Gershel[3] says that almost invariably, prior to admission to an institution, dependent children have lived in poverty for a long period under the poorest hygienic surroundings and have suffered the privation which destitution brings. He has particularly noticed in one of the largest of the Jewish child-caring institutions in New York City that the children at the time they are committed to the institution are ill-nourished and show a poor physical condition. Under these circumstances it is not to be wondered at that deafmute children also show a high percentage of adenoids. Lemcke found lesions of the nasopharynx in 58 per cent.; Aldrich found in 73 per cent. adenoid vegetations; and Wróblewski in 57.5 per cent., Peisson in 50 per cent., and Frankenberger[4] in 59.49 per cent. found hypertrophy of the pharyngeal tonsil.

According to Dr. T. F. Harrington, director of School Hygiene in Boston: "Adenoids will heal themselves in four cases out of five if the child suffering from them is given plenty of outdoor air." After a year's observation at the Hawthorne School, however, I found as the result of the re-examinations of over 300 boys, that in only six cases the moderately enlarged tonsils and adenoids had disappeared and that, although a general subsidence of inflammatory conditions of the tonsils and adenoids under the influence of improved hygienic surroundings was observed, the swellings had in most cases to be removed. A moderate enlargement was even found in four cases, where the condition had formerly been normal.

Examinations of the nose and throat in any institution are useless unless they are systematically followed by the necessary operation, and I claim that the removal of all faulty conditions of the nose and throat will place any institution on a more wholesome, nay, even on a well protected sanitary base. As a matter of fact, the most striking feature of the condition of the Hawthorne School at the end of 1912 was the remarkable improvement of its entire sanitary state, which was the direct result of the large number of operations in 1911. This proves not only the importance of this treatment for the Hawthorne School, but also the advisability of making it a part of the program of every juvenile Reformatory.

## THE USE OF ETHER LAVAGE IN PERITONEAL INFECTIONS.

ABOUT a year ago Morestin (*Bull. et Mem. Soc. de Chir. de Paris*, Feb. 18, 1913) reported a case of extensive soiling of the peritoneum by pus and fecal matter, in which he obtained a cure by copious ether lavage of the entire peritoneal cavity, and remarked that he had long used this method, and had obtained most satisfactory results. One week later, Souligoux again introduced the subject, stating that in 1891 there came under his care a man, both of whose legs had been crushed. He thought nothing could be done but a double thigh amputation, which the patient absolutely refused to consider. Consequently, he washed the wounds with ether, applied splints, and was surprised to find that no suppuration followed, and the patient saved his legs. Since then he has used ether regularly for cleansing superficial infected wounds and in the treatment of erysipelas and lymphangitis. Since 1891 he had put ether into the peritoneum of guinea-pigs without there being any ill effects, but had not dared to try the experiment in man before last year. In July, 1912, he operated upon a patient having intestinal perforation, and found the peritoneal cavity full of pus and fecal matter. "At this moment," said Souligoux, "considering my patient as lost, remembering my old experience of 1891, and knowing that Morestin often employed ether in abdominal operations, I poured in ether in abundance." The patient recovered. So since then Souligoux had applied ether abundantly in all his abdominal cases where there was pus, and with the best of results. Souligoux also reported 31 cases for Marcille: 6 cases flooding of the peritoneum from ruptured tubal pregnancy, all cured; 17 cases strangulated hernia, all cured; 3 rupture or cut intestine, 1 death, 2 cures; 3 cases general peritonitis, 1 death, 2 cures; 1 case infarction large intestine, 1 death; 1 case perforation of stomach by ulcer, cure. It is not definitely stated, and it does not appear probable, that there was peritoneal infection in all of these cases. In the discussion Cunéo said that he had used ether dressings to good advantage in the treatment of felon and phlegmons of the extremities, but that the idea of turning ether into the peritoneal cavity did not appeal to him at all, and he believed that the success obtained by Souligoux was due to the earliness of operation rather than to the employment of ether lavage. At one of the May meetings of the same society (*Revue de Chir.*, June, 1913) Témoin reported two cases in which he had used ether for peritoneal lavage, once when there had been soiling with fecal matter from rupture of the cecum, and once following intraperitoneal rupture of a pyonephrotic sac, both cases resulting in cures. Morestin referred to his experience with the intraperitoneal use of ether since 1901, and insisted upon its antiseptic, tonic, and anesthetic action in this situation. Auvray had used ether successfully in a case of diffuse peritonitis after intestinal perforation. Broca (*Revue de Chir.*, December, 1913) reported that he had tried this method of treatment, and that he was favorably impressed with the results; but in four cases he had observed secondary occlusion of the intestine by adhesion bands. Savariaud also had one case of occlusion after its use. Souligoux reported one more case of his own and 8 for Témoin, all of severe peritoneal infections, and all cured with ether lavage.

So much for case reports and discussion before the Société de Chirurgie. We find no mention of the subject during the past year in the leading American journals, while in the *Lancet* we find but three references, principally covering the work reported above. Phélip and Tartois, however (*Ann. de gynéc. et d'obst.*, December, 1913), have contributed a rather extensive article based upon the report of 16 cases in which ether was used for peritoneal lavage, and a comparison with the last 16 cases said to have been operated upon under like conditions before the employment of ether. The 16 cases were classified as follows: 1 case subacute appendicitis, residual abscess, cured; 3 cases acute appendicitis, localized abscess, 2 cured and 1 died; 7 cases acute appendicitis, perforation, general peritonitis, 3 cured; and 4 died; 5 cases acute appendicitis, without perforation, general peritoneal reaction, 3 cured, 2 died.

Of the 7 fatal cases in this series, one patient was practically moribund when operated upon, and died two hours later. Another patient forced out a coil of intestine when the wound was being dressed on the third day, and this was followed by vomiting, rise of temperature to 104°, aggravation of the general symptoms, and death on the following day. The remaining five cases and a few that were not fatal present certain features of especial interest. Bronchopneumonia occurred in three cases, with two deaths. In one of these there was a beginning pneumonia before operation. The lesion in the lungs increased in extent, and the patient died on the third day after operation. The night before death occurred, however, the face had appeared "leaden," and there had been vomiting of greenish material. In the second fatal case with pneumonic symptoms the patient died on the day after operation with extreme congestion of the entire left lung, though there had been no pulmonary signs before operation. In the sixteen cases without ether lavage of the peritoneum one death from double bronchopneumonia is reported.

Secondary hemorrhages occurred in three cases. One patient died from intestinal hemorrhage five days after operation; in another the hemorrhage occurred on the 17th day after operation from ulceration of the deep epigastric artery, and was controlled by suture after opening up the lower end of the wound; in the third case severe hemorrhage came from the depths of the drainage area on the seventh day after operation, but yielded to tamponnade. Secondary intestinal obstruction occurred in two cases and resulted in the death of the patients. Fecal fistula developed in three cases, only one of these being small enough to close spontaneously. The authors ascribe the death from intestinal hemorrhage to "des phénomènes d'intoxication secondaire"; but while this may explain the death, to the authors' satisfaction, these three cases of hemorrhage remind us very forcibly of the experience of Weir, McBurney, and others when they used plain ether for rectal anesthesia. The same may be said regarding the formation of three fecal fistulæ in nine surviving cases, for extensive sloughing as well as hemorrhage was noted by Weir and McBurney at that time. In the 16 cases without the employment of ether lavage, with which the authors are supposed to have compared the 16 which they report, there were 6 recoveries and 10 deaths. However, no histories or descriptions of conditions found at operation are given of any of these cases. A number of the cases included by Philip and Tartois in their series were such as would almost unquestionably have recovered at the hands of any competent operator, some with and some even without drainage. It is also to be noted that in only 7 of the acute cases was there perforation of the appendix, and in 4 of these death occurred.

In view of all these facts, and since no information is given as to the bacteriology of the free peritoneal fluids, the conclusions formed by the authors would seem to be founded more on enthusiasm in the development of a new idea than upon any convincing basis of fact. We trust that, for the present at least, experimentation along this line will be left to our French brethren; and that the method will not receive trial in this country until much more conclusive evidence of its value has been furnished by its sponsors abroad.

## STUDIES ON ADRENALIN GLYCOSURIA.

A NUMBER of important results have been obtained in the investigations carried on by Anastazy Landau and reported in the *Zeitschrift für klinische Medizin*, Vol. 79, Nos. 3 and 4. He found that whereas 150 grams of grape sugar increase the sugar content of the blood, this increase is as a rule insufficient to evoke glycosuria. If adrenalin is injected subcutaneously it gives rise to glycosuria provided that immediately before the injection the organism receives a considerable amount of grape sugar or of foods containing it. In this case the glycosuria is accompanied by a marked hyperglycemia. If, instead of grape sugar, levulose is administered, no glycosuria results.

Another important observation made is that the glycosuria-producing and the diuretic powers of adrenalin are quite independent of each other. Moreover small doses of cocaine sensitize the action of adrenalin, increasing both the hyperglycemia and the glycosuria. On the other hand a preparation containing the total alkaloids of opium, if injected with adrenalin, inhibits the glycosuria-producing powers of the latter. The mechanism of this inhibition is twofold. On the one hand the opiate delays the mobilization of the glycogen in the liver and reduces the hyperglycemia; on the other hand it diminishes the glycosuria by impairing the secretory activity of the kidneys.

The above facts are pregnant with significance from the viewpoint of the mechanism of diabetes and its treatment. There can be little doubt that a derangement of the internal secretions is at any rate in part responsible for this condition, and that possibly an excess of the internal secretion of the suprarenal capsules or of some allied gland is an important factor in the production of diabetes. There is another necessary component in the nexus of adrenalin-glycosuria, namely, the intake of a sufficiently large quantity of grape sugar. In other words the dietetic factor in diabetes is an important one. Another fact brought out by the experiments of Landau is that the therapeutic value of opium in diabetes may in part be due to a harmful effect of this substance upon the renal epithelium.

## TUBERCLE BACILLI IN THE FECES.

THE text-books of clinical pathology, as a rule, state that while tubercle bacilli may be found in the feces, they are extremely difficult to differentiate morphologically from other acid-fast bacilli, such as the hay bacillus and the smegma bacillus, which are often present. Such a differentiation would no doubt be very difficult, but the statement that acid-fast bacilli constitute a frequent finding in the feces of healthy individuals would seem not to be borne out by the literature. Laird, Kite, and Stewart (*Jour. Med. Research*, 1913, XXIX., 31) considered this aspect of the question in the course of an investigation which they made of the stools of patients suffering from pulmonary tuberculosis. They conclude that acid-fast bacilli have not often been found in the feces of healthy persons. They examined the feces of 153 patients, all of whom were suffering from pulmonary tuberculosis in one form or another. In 101 of these specimens they were able to demonstrate acid-fast bacilli, and in 48 instances proved the identity of the tubercle bacillus by guinea-pig inoculation. They had no autopsies. The swallowed sputum is the most natural and probable origin of these organisms, and they believe that nearly all patients with tubercle bacilli in the sputum also have virulent tubercle bacilli in their feces, while very few who do not have the bacilli in their sputum have acid-fast bacilli in their feces. They refer, however, to the work of Rittel-Wilenko, who in a series of twenty-nine autopsies found that ulcers were almost always to be found in the intestine if acid-fast bacilli had been found in the feces, and think that such ulcers are much more common than is generally supposed. In view of these findings it would seem to be important to disinfect the stools as carefully as the sputum. The danger of contaminating water supplies is really greater than in the case of the typhoid bacillus, because of the greater resistance of the tubercle bacillus. The hypochlorite treatment of drinking water would

probably have little effect upon any of the acid-fast bacilli, and in sewage they would probably remain virulent for a longer time than the majority of the pathogenic bacteria. This matter has always been neglected in the past, but would seem to demand more attention in the future.

### Malignant Disease in Animals.

It is only within the past few years that any very reliable knowledge has been acquired with regard to malignant disease in animals. During the last decade, however, a good deal has been learned in this direction for it has now been discovered that it is universal in all vertebrate animals. Ernest Glynn in a paper contributed to the *Medical Press and Circular*, Feb. 11, 1914, points out that neoplasms were found in 162 out of 67,849 bovines slaughtered in Great Britain in 1910. The Imperial Cancer Research examined 160 neoplasms microscopically; 120 proved to be cancer and 29 sarcoma. Malignant disease may occur in the horse, the sheep, the pig, the elephant, the cat, the dog, the hen, and even the trout, and the cod. Glynn draws attention to the fact that the discovery of the broad zoological distribution of cancer amongst vertebrates has been of great value in regard to certain aspects of the cancer problem. Especially interesting has been the study of cancer in mice, which are particularly susceptible to it. It has been discovered that cancer is capable of being transplanted from mouse to mouse. Further, mice can be protected from developing experimental cancer by a form of vaccination, as cattle are protected against anthrax. Glynn thinks that it is possible that some day this principle of protective inoculation may be applicable to the prevention or treatment of malignant growths in man, though how far one can argue from mice to men is very uncertain. The problem of cancer is the greatest, taking all the factors of the case into consideration, which confronts the medical profession at the present time, and the mystery pervading the origin of the disease can perhaps be laid bare only by experimental research on animals and by studying the malady in men and animals. No doubt the antivisectionists will oppose experimental research in animals, even if it promises to lead to the discovery of the origin of cancer and hence to the prophylaxis and cure of the disease as strongly as they have antagonized all experiments on animals. They place animals before men and despite the fact that experiments on animals have been shown to pave the way to discoveries resulting in saving of life and restoration to health in animals as well as in man, they still continue to carry on their ill-considered agitation.

### Another Antivivisection Romance.

Some of the antivivisectionists of New York or others of the same breed have recently caused the circulation of stories to the effect that children treated in the city hospitals have been inoculated with dangerous diseases as a part of the experimental work done in the hospitals. These stories have been investigated and as a result Health Commissioner Goldwater has issued the following statement: "Not only were the children found not to be suffering with the diseases alleged, but it was also shown that there was absolutely no experimental work in any of the diseases with which it was charged they had been inoculated in any of the hospitals of the Department of Health. The charge was made that many of the children attending the public schools in the Bronx were suffering with disease due to experimentation and infection in city hospitals. In particular, B. S. Deutsch addressed a letter to the District Attorney of Bronx County in February, stating that forty-eight children, many of whom were attending the public schools, were suffering with a grave disease. Mr. Deutsch's statement goes on to say that the alleged infection of these children was the result of 'inoculation which occurs without the consent of either the children or their parents, or else as a result of negligence or carelessness within the hospitals.' The department investigators visited the forty families mentioned in the Deutsch list. Of this number fifteen could not be found at the addresses given. Interviews were obtained with twenty-five families, in which there were thirty-four children. Among these not a single case of the disease suspected was found. There was no evidence of the inoculation of any of these children with serum or vaccine. Time and again statements made by the antivivisectionists have been proven false, and yet the propagandists continue to make them."

## News of the Week.

**Annual Report of Canal Zone.**—The Department of Sanitation of the Isthmian Canal Commission reports that during the year 1913 the employees of the Isthmian Canal Commission and the Panama Railroad Company numbered 56,654, and that among these there occurred during the year 473 deaths, giving an annual death rate per 1,000 of 8.35, the lowest on record. For 1912 the rate was 9.18, and for 1911, 11.02. Among white employees from the United States the death rate from disease was only 2.50 per 1,000, while the total death rate for the year among those classed as employees was 5.0 as against 5.52 per 1,000 in 1912. The inclusion of American women and children raised the death rate from disease among Americans to 3.40, but the inclusion of the officers and men of the United States Army and Marine Corps stationed on the Canal Zone, and their families, lowered the rate again to 3.16 per 1,000. Of the deaths among employees during the year, 4 were due to typhoid fever, 6 to dysentery, 47 to pneumonia, 21 to malaria, 24 to organic disease of the heart, 65 to all forms of tuberculosis, 26 to nephritis, and 176 to external violence. Among the 11,943 white employees there were no deaths during the year from either dysentery or typhoid fever. For the total population of the cities of Panama and Colon and the Canal Zone, the death rate per 1,000 for 1913 was 23.57, an increase over 1912 when the rate was 20.49. One man with smallpox on a ship from Callao, Peru, was isolated at Santo Tomas Hospital during the month of November, and subsequently recovered and was discharged the following month. With this exception no case of yellow fever, smallpox, or plague originated on or was brought to the Isthmus during the year.

**England's Low Birth Rate.**—During 1913 the birth rate per 1,000 in England was 23.87, or 0.02 points lower than that for 1912, which was the previous low record. The death rate for the year fell also from 13.32 in 1912 to 13.07 in 1913, while the marriage rate increased from 13.5 to 15.51.

**Plague in Havana.**—Because of the discovery of a case of supposed bubonic plague in Havana on March 6, the departure of all vessels from the port was prevented by the Marine Hospital Service. It is reported that plague is prevalent in all the ports of Ecuador, and that a number of deaths have occurred.

**New York's Birth Rate.**—The city's birth rate for the year 1913 was the lowest on record since 1903, reports the Department of Health. The total number of births during the year was 135,134, making a rate of 25.12, against a total of 135,666, and a rate of 26.22 in 1912, or a decrease in the absolute figures of 532 births, and in the rate of 1.07.

**Vital Statistics in New Jersey.**—The New Jersey State Board of Health reports that during the month ending February 10 the deaths throughout the State numbered 3,761, of which 665 were due to circulatory diseases, 441 to pneumonia, 363 to tuberculosis, 55 to diphtheria, 16 to typhoid fever, 38 to measles, 22 to scarlet fever, and 35 to whooping cough. There were 661 deaths of infants less than one year of age, 273 of children between one and five, and 1,316 of persons of sixty years and over.

**City Death Rate.**—For the week ending February 28 the death rate in New York City was 16.93 per 1,000 of population, the total number of deaths being 1,812, as against a rate of 16.50 and a total of 1,699 deaths in the corresponding week of 1913. For the first nine weeks of 1914 the death rate was 15.08 per 1,000, as compared with 15.47 for the same period of 1913.

**Fordham Medical School Rated Up.**—Announcement has recently been made that the Council on Medical Education of the American Medical Association, which in 1912 reduced the School of Medicine of Fordham University, New York, to the Class B grade, has now restored the school to the A grade.

**Typhoid in Canada.**—Typhoid fever is reported to be epidemic in Sabrevois County, Province of Quebec, where out of a total population of 7,000 people, 2,000 are suffering from the disease. Most of the cases have thus far been of a mild type, although several deaths have occurred. It is believed that the water and milk supplies are the sources of the contagion.

**For Hospital Organization.**—The Board of Health of New York City on March 3 adopted a resolution requesting the medical boards of the Willard Parker and the Kingston Avenue, Brooklyn, Hospitals, to appoint a conference committee to formulate a plan of organization to meet the needs of these hospitals for contagious diseases and of the two contemplated hospitals in the Bronx and Queens. The committee was urged to consider the following points with a view to improving the medical service at these hospitals: (1) A definite term of appointment, not to exceed three years, for each member of the visiting staff, the appointment to be subject to renewal. (2) A continuous period of duty of not less than three months. (3) A clear definition of the duties of members of the visiting staff. (4) A plan which will provide for a visit by a member of the visiting staff to every ward at least once daily. (5) An auxiliary staff of special consultants.

**Fewer Street Accidents.**—Fewer persons were killed in the streets of New York by traffic accidents during February than in any month since February, 1911, according to the report of the National Highways Protective Society, which believes that the decrease was due largely to the heavy snow in the streets which prevented speeding. During the month eight persons were killed by automobiles, ten by trolley cars, and two by wagons.

**A Conference on the Cost of Clean and Wholesome Food** will be held at the N. Y. Academy of Medicine on March 19, at 4 P.M. The speakers will be Dr. Haven Emerson, Dr. Marian McMillan, Miss Cauble, Miss Goldmark, Messrs. P. E. Taylor, A. D. Woodruff, and F. A. Harne. In the evening of the same day the regular meeting of the Academy of Medicine will be devoted to a discussion of food in general, the speakers being Drs. Bigelow, Pennington, Lusk, Mendel and others.

**Harvey Lecture.**—The tenth lecture of the Harvey Society will be delivered on Saturday, March 14, at eight-thirty, at the New York Academy of Medicine, 17 West 43d street, by Prof. W. T. Halsted of Johns Hopkins University, on "The Significance of the Thymus Gland in Graves' Disease."

**Civil Service Examinations.**—Open competitive examinations for various positions in the State and County services will be held in several cities throughout New York State on March 28, 1914. The positions are as follows:

*Trained nurse* in State institutions, open to both men and women, at a salary of $420 to $600 and maintenance. Candidates must be graduates of a nurses' training school registered by the State Education Department. No written examination will be held, but candidates will be rated on age, education, preliminary training, and experience.

*Assistant physician* in the State Homeopathic hospitals at Middletown and Gowanda. The usual salary is $900, increasing to $1,200 and maintenance. The examination is open to both men and women who are graduates of a registered medical school, have had one year hospital experience or three years private practice, and are licensed to practice in New York State. Unmarried men are preferred.

*Physician*, Rensselaer County Jail, at a salary of $350 a year. Candidates must be licensed physicians of New York State. Intending candidates for any of the above must execute application blanks and file them in the office of the State Civil Service Commission, Albany, N. Y., on or before March 20, 1914. Application blanks will be supplied on request at the office of the commission until March 18.

**International Surgical Association.**—The fourth congress of this association will be held at the Hotel Astor in New York City lasting four days, beginning Monday, April 13, 1914. This is the first time that the congress has ever had a meeting outside of the city of Brussels, where the first one was held in 1905, and repeated every three years. The membership of the Association is limited to a certain number from each country. The membership in the United States is about one hundred. The president of the Fourth Congress is Professor Depage of Brussels, Professor Willems of Ghent is president of the International Committee, and Dr. L. Mayer of Brussels is the General Secretary. The local secretary is Dr. J. P. Hoguet, 40 East Forty-first street, New York City, and the American committee is composed of Dr. Roswell Park (deceased) of Buffalo, Dr. L. L. McArthur of Chicago, Dr. C. L. Gibson of New York City, and Dr. R. H. Harte of Philadelphia. These last three

with the addition of Dr. Rudolf Matas of New Orleans and Dr. R. G. LeConte of Philadelphia constitute the committee designated to represent the American Surgical Association in making preparations for the entertainment of the foreign members. The program is limited to the consideration of three main topics: (1) "Gastric and Duodenal Ulcers," by De Quervain of Basel, Hartmann of Paris, Lecene of Paris, Mayo of Rochester, Minn., Moynihan of Leeds, and Payr of Königsberg. (2) "Grafts and Transplantations," by Morestin of Paris, Villard of Lyons, Ulmann of Vienna, Lexer of Jena, and Carrel of New York. (3) "Amputations," by Witzel of Düsseldorf, Ceci of Pisa, Kuzmik of Budapest, Binnie of Kansas City, Durand of Lyons, and Ranzi of Vienna. After the close of the congress most of the foreign members will make a tour of other cities, the itinerary including Philadelphia, Baltimore, Washington, Chicago, Rochester, Minn., Montreal, and Boston. The foreign members have been invited also to attend the session of the American Surgical Association held in New York at the Hotel Astor April 9, 10, and 11, and many have signified their intention of arriving on the SS. *Imperator* due April 9.

**Courses in Psychiatry.**—A course of special instruction for physicians engaged in psychiatrical work will be given at the Psychopathic Hospital of the University of Michigan, Ann Arbor, extending over a period of four weeks from March 30 to April 25, 1914. Instruction will be given in clinical lectures and conferences, laboratory studies, and demonstrations, and will include all phases of the subject. A fee of twenty-five dollars will be charged for the course, and the number of students will be limited to fifteen. Further details may be obtained upon application to Dr. Alfred M. Barrett, Director of the Psychopathic Hospital, Ann Arbor, Mich.

**Personals.**—Dr. Charles F. Sanborn has been appointed superintendent of the new Cincinnati General Hospital, Cincinnati, O. The appointment was made on the basis of a civil service examination.

At a recent meeting of the Tri-State Medical Society of the Carolinas and Virginia, Dr. E. C. Register, editor of the *Charlotte Medical Journal*, was elected president.

**Dr. Georg Joachimsthal**, professor of surgery and director of the Poliklinik für orthopädische Chirurgie in the University of Berlin, died on March 1, from inflammation of the lungs, at the age of fifty-two years.

**Mr. Henry Green** of Hartford, Conn., one of the pioneer workers with the *x*-rays, died at his home from cancer induced by the rays, after a long illness, on March 4.

**The Late Dr. William Kelly Simpson.**—The following resolutions were adopted at a meeting of the Medical Board of the New York Foundling Hospital:

Dr. William Kelly Simpson came into the New York Foundling Hospital in the days when Dr. Joseph O'Dwyer was perfecting intubation. He was, in fact, the first one to intubate an adult, at the request of Dr. O'Dwyer. For many years Dr. Simpson cheerfully responded to all calls from the hospital for the Sisters of Charity as well as the children. It is in grateful remembrance of these services that the medical board wishes to make this record.

While recognizing his well-known skill and professional services, the medical board desires to make mention of his good comradeship, his cheery, joy-bringing presence. It has been truly said that in his death the medical profession has lost something of cheerfulness in the daily toil of all those who knew him.

*Whereas*, The Medical Board of the New York Foundling Hospital has lost a much prized counsellor and friend in the death of Dr. Simpson; therefore be it

*Resolved*, The Board herewith records its high appreciation of him as a consultant, of his untiring devotion to the hospital, and of his genial presence.

*Resolved*, That a copy of these resolutions be spread upon the minutes of the Board and that a copy be sent to each of the current weekly journals of medicine, and that a copy of the same be sent to the family.

W. P. Northrup, *President*,
Colman W. Cutler, *Secretary*.

**Obituary Notes.**—Dr. Francis Martin Burke of Brooklyn, N. Y., a graduate of the New York University Medical College in 1890, died at his home from diabetes on March 3, aged 53 years.

Dr. Frank Sargent Grant of New York, a graduate of the College of Physicians and Surgeons, New York, in 1875, died at his home after a short illness on March 1, aged 62 years.

Dr. Heber McK. Harvey of Washington, D. C., a graduate of the Bellevue Hospital Medical College, New York, in 1867, for some years a practising physician of Evansville, Ill., and for several years county physician of Vanderberg County, and a member of the Medical Society of the District of Columbia, died at his home in Washington after a long illness on February 19, aged 74 years.

Dr. John F. Welch of Quincy, Mass., a graduate of the Bellevue Hospital Medical College, New York, in 1880, a member of the American Medical Association, the Massachusetts Medical Society, and the Norfolk South District Medical Association, formerly city physician of Quincy, and a member of the Board of Health, consulting physician to the Quincy Hospital, and first president of the Anti-Tuberculosis Society of Quincy, died at his home on February 23, aged 59 years.

Dr. William Wallace Stevens of Kansas City, Mo., a graduate of the University Medical College of Kansas City in 1901, and a member of the American Medical Association, and the Missouri State and Jackson County Medical Societies, was killed in an automobile accident, on February 18, in the 34th year of his age.

Dr. William R. Gieser of Philadelphia, a graduate of the Hahnemann Medical College and Hospital of Philadelphia in 1892, died at his home on February 26, aged 55 years.

Dr. William Endlich of Philadelphia, a graduate of the Jefferson Medical College, Philadelphia, in 1885, died at his home on February 27, aged 55 years.

Dr. Alfred Carty Stratton of Florence, N. J., a graduate of the Medico-Chirurgical College of Philadelphia in 1913, died at the Philadelphia Hospital for Contagious Diseases from scarlet fever contracted in the course of his professional duties, February 26, aged 24 years.

Dr. Hiram J. Coon of Colfax, Ind., a graduate of the Medical College of Indiana, Indianapolis, in 1881, died at his home from apoplexy on February 27, aged 62 years.

## OUR LONDON LETTER

(From Our Special Correspondent.)

DISEASES OF CHILDREN—DISCUSSIONS ON TWO SECTIONS AND EXHIBITS—SPLENECTOMY—DWARFS OR MONSTERS?—MEDICAL VOLUNTEERS.

London, Feb. 20, 1914.

Diseases of children have attracted a good deal of attention lately. At the section of the R. S. M. cases and specimens have been exhibited and contributions made. Kala azar in a boy of five whose father had recently died from that disease attacked the lad when in Calcutta in March, 1913. When he reached England in June the abdomen was enlarged and it has continued to increase since while wasting has gone on, especially in the chest and limbs. Glands enlarged, cervical, axillary, and inguinal. Abdomen measured 24½ inches in circumference, liver up to 3 inches below costal cartilage, spleen enormous, reaching middle line and filling left iliac fossa. The blood count was given by Dr. Whipham as: Red cells, 3,220,000 per c.mm.; white cells, 2,200; polymorphonuclears, 46 per cent.; leucocytes, 38 per cent.; large mononuclears, 12 per cent.; transitionals, 4 per cent.; hemoglobin, 66 per cent.

A case of lymphatic leucemia in a boy of 6½ treated by benzole was shown by Drs. Rolleston and Boyd. Enlargement of the cervical glands followed measles and pneumonia. Later the axillary, inguinal, and submaxillary glands enlarged and the spleen was palpable. The boy was treated at first with 2 minims of benzole t.i.d., and then the dose was increased later to 3 minims. The following figures were given, taken at a month's interval:

| | December. | January. |
|---|---|---|
| Leucocytes ..... | 60,000 | 16,000 |
| Large lymphocytes..... | 54 p. c. | 41.5 p. c. |
| Small lymphocytes ..... | 16.5 p. c. | 46 p. c. |
| Polymorphonuclears .... | 25 p. c. | 10 p. c. |

At an earlier meeting there was a discussion on enlargement of the spleen in children, which Dr. Robert Hutchinson divided into nine groups, but others thought so elaborate a classification was not required. One of the commonest disorders of early childhood is the so-called splenic anemia of infancy—pseudo-leucemia of von Jaksch—and the problems that arise about it are not very different from those in adults. In later childhood cases are not to be distinguished from splenic anemia in adults. Cases combined with cirrhosis—a rather frequent condition—Dr. Hutchinson classified thus: (a) The cirrhosis of multilobular type, some alcoholic, though probably other poisons may produce the same or a similar result; (b) monolobular (Hanot type); (c) syphilitic; (d) cases of enlargement lasting for years, followed by a multilobular cirrhosis (Banti's disease); (e) cirrhosis, depending on congenital malformation of the bile ducts. Splenectomy is now enabling one to consider and may determine how far the part played by the spleen is active or passive. The operation is indicated in neoplasms, cysts, and some cases of splenic anemia in adults and splenomegaly, with acholuric jaundice.

Sir J. Bland-Sutton pointed out how rapidly the spleen increases after birth and easily becomes engorged in fevers and other diseases, especially rickets, suggesting that it has important functions at this early stage of life. Splenic anemia he attributed to its functional excess of activity. He had removed the spleen of a woman aged twenty-two for acholuric jaundice with a satisfactory result, and in children he regarded the operation as a life-saving one for splenic anemia. Dr. Sutherland related two cases, each a family disease, splenectomy proving a complete cure in each. Dr. Poynton thought he was the first in this country to show the yellowness might alternate with anemia, but be so slight as to be easily overlooked in members of the same family. He pointed out the difficulties of diagnosis. Dr. Thursfield said the disease was really a congeries of cases due to different causes. In obscure cases a surgeon might be asked to remove the spleen, for in the vast majority of splenectomies he believed the whole of the splenic tissue was not removed. Mr. Philip Turner mentioned an obscure case in a boy of five, in which splenectomy was most successful, the boy being quite well three months after it. Dr. Lerkis discussed the fragility of the corpuscles and vital staining granules. Dr. P. Weber proposed to substitute the word abnormality for enlargement of the spleen, and classified them as (1) when the change served some useful purpose, (2) due to tumors, (3) to microbes, (4) to excessive functional activity.

The Clinical Section's last meeting was also occupied with the subject of splenectomy. No less than sixteen cases of various abnormalities for which operation has been performed or is contemplated were brought forward for consideration. Dr. Whipham described four of splenic anemia in one family—father and three children—and said splenic anemia was rare in two successive generations. The blood counts in the four were similar; the red cells decreased and altered in size, shape and nucleation. There was also eosinophilia, possibly due to tenia in the father but not in the children. Splenectomy had to be considered in the two girls who had got worse lately, but not in the boy or the father. Mr. P. Sargent showed a girl of ten who recovered from the operation, but six weeks afterward suffered from hematemesis, pyrexia, and diarrhea, but after thirteen weeks was well. Mr. G. Hoffman showed a similar case in a girl of twelve, who had in addition epistaxis, purpura, and melena. The blood condition was normal two years later. Drs. French and Turner showed a boy of five who had recovered rapidly after splenectomy. A younger sister had similar symptoms. Antisyphilitics had been tried unsuccessfully. Sir J. Bland-Sutton advised operation for the boy shown by Dr. Whipham. Dr. G. R. Ward did not agree to the diagnosis in the family group, but held that the slight yellowness was due to acholuric jaundice which the blood counts supported. Dr. Parkes Weber was of the same opinion. When adults and children in a family had enlarged spleen and anemia the condition was hemolytic jaundice, though yellowness was not apparent. Sir W. Osler thought the remittent fever with eosinophilia in Dr. Whipham's case indicated trichinosis. He had long advocated operation for splenic anemia. Dr. Box had formerly treated Dr. French's case and a similar one, regarding them as von Jaksch's anemia. Cases of recovery after splenectomy for acholuric and hemolytic jaundice were shown and discussed by several members. Dr. Wynter said in such cases excess of cells appeared at first, but

soon subsided as if for compensation for a time. In considering operation he would regard not only the mortality, but the chance of enjoying a full life afterwards. Dr. Thursfield had a case of congenital acholuric jaundice cured by operation, and insisted the differential diagnosis, which he thought could be made definite by fragility of red corpuscles. But Sir B. Dawson reported cases without fragility and said the jaundice was due to overproduction of bile pigments and it was a function of the spleen to manufacture the precursors of these pigments. Fragility persisted after splenectomy. In hemolytic jaundice "bilious attacks" occurred with bile in the urine. In such he explored the gall bladder and commonly found gallstones or inspissated bile which demanded attention first. A large spleen was not a necessary symptom, though it was usually found in young patients. Dr. P. Weber suspected increased fragility might be due to bile pigment without bile salts. In obstructive jaundice both were present with increased resistance.

Dr. Galloway invited opinions on a case of Banti's disease he brought, and several speakers favored splenectomy. Dr. Spanton said the mortality of splenectomy was 75 per cent. in 1866 to 1875; it was 59 per cent. in 1870 to 1885, and in 1886-1895 it was 16 per cent.

Professor Keith's picture of pretty dwarf, fairy and elf babies as the origin of our race, mentioned in my last, has given place to a different view of evolution. For in this week's lectures at the College of Surgeons he says the blood relationship between man and the great anthropoid apes (gorilla, chimpanzee, orang) is becoming more apparent and certain. At one time it might be, he said, that the family hominidæ was composed of diverse genera as that of the anthropoids and had a restricted distribution like them. Recent geological discoveries revealed the former existence of human types so different in structure as to represent separate genera of men. In another lecture on Wednesday he dealt with the brain development of anthropoid apes dwelling on the differences from that of man. All very interesting, but perhaps less inviting than the miniature babies from which the professor hinted human infants might have developed. They could hardly go in both directions. Is it to be the tiny growing bigger or the monster becoming smaller in order to develop mankind? This is a question we must ask the evolutionists to settle for us.

The Cantlie Club, formed in honor of Mr. James Cantlie's work in founding the Medical Volunteers, held its third annual dinner on Saturday, when over 100 well-known officers connected with the several branches of medical volunteering assembled. Lt.-Col. Whart, commanding the Third London Field Ambulance, took the chair, testified to the efficiency and camp discipline, comparing it favorably with the regulars. Col. Cantlie recalled that, though the Medical Volunteers were not officially recognized until 1885, they were started previously by some fellow-students with himself. When enrolled, in defiance of authority, they insisted on wearing their round cap and broad red trouser stripes, instead of the authorized narrow ones, and they started a fife and drum band. He could confess now that these breaches of discipline were committed at the instigation of certain medical officers in the War Office and used to obtain similar privileges for the regulars. That was how the R. A. M. C. got their uniform and band.

## MAGNESIUM SULPHATE IN TETANUS.

To the Editor of the Medical Record:

Sir:—Under the headline, "Magnesium Treatment of Tetanus," there is in the issue of the Medical Record of February 21, 1914 (page 355), an abstract of Stadler's article on that subject. The abstract contains an erroneous statement. It reads: "Stadler concludes his article as follows: He and others tested Meltzer's method in the Balkan War. There were no recoveries reported, but death resulted in three of five cases from cardiac failure and not from tetanus." The sense of the last sentence is obviously this: No recovery occurred under treatment with magnesium sulphate, while three of five patients died from heart failure and not from tetanus. The last part implies the further conclusion that the injections of magnesium salts not only were of no avail, but may have been the cause of the heart failures and deaths in three of the cases.

Now permit me to give here the exact translation of the paragraph under question in Stadler's article (*Berl. klin. Wochenschr.*, 1914, p. 113). It is as follows: According to my knowledge Meltzer's method was applied on a battle field for the first time by one of the Swiss sanitary expeditions in the Turko-Bulgarian War. Pettavel, one of Kocher's pupils, reports five very severe cases of tetanus with short incubation periods which were treated at the field hospital Kirkilisse with intraspinal injections of magnesium sulphate. Of the five patients three died of heart weakness; the heart action of these three patients, however, was very bad when they were brought into the hospital. Of all cases of tetanus at Kirkilisse and Demotica that were treated by any other method none survived."

In other words, of five cases of severe tetanus which were treated with intraspinal injections of $MgSO_4$ two recovered; the three which did not recover did not die from tetanus, but from cardiac failure, from which they suffered before the injections of the magnesium salts were made. Furthermore, on that battlefield no case of tetanus treated by any other method recovered.

According to the abstract, no recovery from tetanus took place under magnesium treatment which, on the contrary, may have been the cause of death of three cases in which it was applied; the unavoidable conclusion to be drawn from such an experience can be no other than that the magnesium treatment is not only useless but dangerous and therefore ought to be avoided. According to Stadler's actual statement, two out of five recovered under the magnesium treatment, the other three had hardly any chance of recovery on account of the preexisting heart failure; while no recovery occurred under any other mode of treatment of tetanus; evidently the conclusion to be drawn from this version ought to be that magnesium treatment is to be highly recommended in tetanus. That is indeed the outspoken opinion of Stadler in the paper under discussion; of Pettavel, who made the quoted observations, and of Kocher, whom some writers call now the "second father" of the magnesium treatment and who communicated to me verbally last summer the "excellent results" obtained on the battlefield with this treatment.

S. J. Meltzer, M.D.

Rockefeller Institute,
New York.

## THE ADHESION-PRODUCING BACILLUS.

To the Editor of the Medical Record:

Sir:—Allow me to protest against the name *B. adhæsioformis* which Dr. Bassler has "taken the liberty" of tacking on to his new (?) bacillus. *B. adhæsioformis* means (if it means anything at all) a bacillus which is shaped like an adhesion. A bacillus which forms adhesions should be called *B. adhæsioformans*, or *B. adhæsiofaciens*.

R. J. E. Scott, M.D.

New York.

1. A Study of Some Types of Disturbance of the Stomach and Intestines Associated with Adhesions Involving the Intestinal Tract and Their Treatment. H. F. Hewes.
2. Serodiagnosis of Pregnancy. A. Review. A. K. Paine.
3. The Effect of "606" on the Eye, with the Report of Seven Cases of Serious Eye Complications Following Its Use. P. S. McAdams.
4. The Early Diagnosis and Treatment of Dementia Præcox. E. Mellus.
5. Diabetes and Surgical Operations. C. G. Cumston.
6. The Significance of Earache. I. Sobotky.

**1. Disturbances of the Stomach and Intestines Associated with Intestinal Adhesions.**—H. F. Hewes states that with the great diversity in the location of adhesions involving the gut, and in the forms of distortion which they cause, and with the complicated manner of action of these abnormal conditions upon functions, it is clear, *a priori*, that the symptomatologies found in association with this condition of adhesions causing disturbance in the body must be very varied. A majority of the various symptomatologies found in association with adhesions, or distortion or disturbance of the gastrointestinal tract due to adhesions, are clearly in no sense pathognomonic of this condition, since similar symptomatologies are found in association with other pathological or functional disturbances of the body. For example, constipation with some sign of abdominal discomfort, perhaps the most common symptomatology of adhesions, is a frequent finding of purely functional disturbance of the intestines or of various conditions of organic disturbance other than adhesions. The continuous diarrhea often seen with adhesions is a symptom of functional disturbance, inflammatory colitis, or improper assimilation of food. Alternating constipation and diarrhea is a common symptom of mucous colitis and of nerve disturbances. The stomach symptoms seen with adhesions are often similar to those found in nervous dyspepsia, in some cases of ulcer of the stomach and duodenum, and in gallstones. The diagnosis or probable diagnosis that the symptoms in any given case are the result of adhesions can be made only by supplementing the study of symptoms with an *x*-ray examination, and in case of a positive finding, by exclusion of definite evidence of other conditions capable of causing similar symptomatologies.

**2. Serodiagnosis of Pregnancy.**—A. K. Paine concludes that the Abderhalden test is available where the services of a competent laboratory can be had. It is by far the most accurate method at one's disposal for the diagnosis of pregnancy, comparing favorably as a test with the Widal and Wassermann reactions in their respective fields. Until some method is devised whereby the materials used, especially the prepared placental albumin, may be kept for some time and in a more convenient form, and dependable dialyzers more easily procurable, the test will not be generally available. Attempts are being made to simplify the technique so as to make it more easily applied. Gutman expresses confidence that such a simplification can be accomplished, the difficulty in procuring a special dialyzer being the particular obstacle with which he is contending. The reaction places in one's hands a possible means whereby one may make a remarkably accurate diagnosis of the existence or nonexistence of pregnancy should the exigencies of any case demand a prompt determination of the fact.

**3. The Effect of Salvarsan on the Eye.**—P. S. McAdams states that no case of injury to the healthy eye by salvarsan has been proven. The consensus of opinion is that it is innocuous to the healthy eye. A favorable result from the application of this drug is to be expected in syphilitic disease of the iris, choroid, retina, and optic nerve; in paralysis of the ocular muscles due to syphilis, and sometimes in interstitial keratitis. As far as one can judge in the short time salvarsan has been in use it must be welcomed as an effective specific remedy in syphilis of the eye, which seems especially indicated in cases in which speedy aid is urgent. It is not a panacea for ocular syphilis which can entirely replace the usual specific preparations. It is especially indicated when a speedy action is desired, as in primary ocular affections or in secondary or tertiary symptoms, if a rapid impairment of function is dreaded.

**5. Diabetes and Surgical Operations.**—C. G. Cumston points out that in all cases of diabetes requiring operation, when the latter is not urgent for the saving of life, the patient should first be put upon a strict diet and treatment with drugs. When the glycosuria is sufficiently under control the operation may then be proceeded with. The reflexes should be nearly normal for a good prognosis, although this is not absolutely necessary. The urine should not contain either acetone or β-oxybutyric acid. The presence of urobilin or albumin should be a warning against interference. The quantity of urea secreted should be nearly normal. The length of time required for the operation and the quantity of the anesthetic given should be reduced to a minimum, likewise the loss of blood.

8. Roentgen Diagnosis. J. Friedmann.
9. Carbon Disulphide as a Therapeutic Agent. H. H. Seelye.

**2. Phenolsulphonephthalein as an Indicator of Renal Function.**—M. W. Ware believes that the value of phenolsulphonephthalein as an indicator of renal function has not been proved. The efficiency claimed for the drug because of its complete rapid elimination and its reappearance in an unaltered form cannot bespeak any elaboration in the sense of work done on the part of the kidney, for this is denied by the very definition of efficiency, which represents the ratio of useful work to energy expended. The dye output can be estimated colorimetrically. The interpretation of the colorimetric reaction is the issue. Evidence adduced favors its being an acidometric test, but without any claims of parallelism existing between the degree of acidity and kidney function. Its nonirritating nature, nontoxicity, and smallness of dose, which are all regarded as virtues (Geraghty and Rowntree), are but of the negative variety. As for the information afforded by the test being precise this is controverted by theoretical, chemical, experimental, and clinical evidence, which forbids reliance on the

extravagant claims of phenolsulphonephthalein as a functional kidney test.

**4. The Ross Jelly Film Method in the Diagnosis of Syphilis.**—J. A. Roddy states that E. H. Ross reported the finding in syphilis of protozoal parasites of considerable dimensions and possessing various phases of development, of which the *Treponema pallidum* is one. The technique for examining suspected specimens is as follows: Make 2 per cent. agar by dissolving powdered sugar in distilled water, filtering and sterilizing it. To 5 c.c. of this agar add 0.4 c.c. Unna's polychrome blue, 0.4 c.c. of 5 per cent. aqueous solution of sodium bicarbonate, and 4.2 c.c. sterile water. Pour a thin film of this jelly on a clean slide, and when it is hard place the material to be examined on a clean cover glass and gently drop it on the jelly. Material for examination is collected in capillary tubes and mixed with an equal volume of 1 per cent. citrate of sodium in normal salt solution. The author states that the examination of blood for Ross bodies is not as simple a procedure as has been reported; more than ten minutes should be devoted to the examination of a slide before it is declared negative; it is often difficult to differentiate these bodies from artifacts, sometimes impossible. The value of the test as an aid to diagnosis is greatly reduced by the occurrence of the bodies in the blood of nonsyphilitic patients, or what amounts to the same thing, the occurrence of artifacts difficult if not impossible to distinguish from them. If the bodies described by Ross as *Lymphocytozoa pallida* really are such, then they do not occur in nonsyphilitic patients and the author's positive finding in nonsyphilitic cases raises the question of the nature of the bodies found. It seems equally probable that the bodies described by Ross may not be living parasites, but products of human tissue acted on by toxin; that the toxin of syphilis causes this change very frequently, more frequently perhaps than most others, but that some other toxins also produce these bodies. The Ross bodies are present in the blood of most syphilitics and less frequently present in those suffering from other diseases. Their true nature has not been conclusively established, nor has it been shown that these bodies do not occur in normal persons. The author is convinced that the Ross test is much inferior to the Wassermann test in the diagnosis of secondary and tertiary syphilis and believes that the examination of material from suspected initial lesions for Ross bodies, in addition to examination for spirochetes, will be a valuable aid in the differentiation of chancres and chancroids.

**5. A Method of Determining the Dust in Air and in Fresh Air Schoolrooms.**—J. B. Todd has found after many experiments that the following method has proved satisfactory in giving a positive objective answer to the question of how much dust there is in the air: A canton-flannel disc two and three-sixteenths inches in diameter is placed in a receiver which has a round opening one inch in diameter. Through this, by means of a suction pump, 200 cubic feet of air are drawn. On removing the canton-flannel disc one has the dust record. For the purpose of standardization a scale of ten gradations, from white to black, has been made. The pump used is a rotary quadruple bellows pump from a player-piano.

**3. Ischemic Lumbago.**—J. Ramsay Hunt states that ischemic lumbago is readily recognized and differentiated from all other affections of the back by the following characteristics: In ischemic lumbago there is a sensation of pain or painful cramp, which may be associated with a feeling of weakness or stiffness, localized in the muscles of the lumbar region. This may be bilateral or strictly unilateral in distribution and is limited above by the twelfth rib and below by the crest of the ilium. When severe the pain may radiate as far laterally as the midaxillary line. The painful area is not tender to pressure, except after prolonged exertion, and then it is not of long duration. This pain is characterized by its intermittent character and absolute dependency on muscular exertion. If there is no effort or strain on the muscles there is no pain. When the pain is induced, any posture which places the affected muscles at rest promptly produces relief, and the pain ceases. For diagnostic purposes bending movements of the spine may be used to induce the pain and demonstrate its local and intermittent character. The movements of the spine are normal and in the beginning painless, which is an important distinguishing feature from lumbago of rheumatic origin. In the cases which have come under the author's observation the pain was not influenced by changes of weather, and this may be regarded as another point of difference in differentiating from the rheumatic lumbago, with which it is most likely to be confused. All other affections of the spinal column and pelvic joints may be excluded by the complete freedom of pain in active and passive movements.

**5. Chronic Tuberculous Diaphragmatic Pleurisy with Symptoms Resembling Gastric Ulcer.**—L. S. Mace points out that the presence of pleuritic adhesions between the base of the lung and the diaphragm, causing localized retractions of the latter, may in some instances produce a symptom complex of pain, gas and vomiting resembling the symptoms of gastric ulcer. If such patients are carefully examined for beginning lung tuberculosis, and it is borne in mind that the phrenic plexus and lower intercostal nerves may transmit pain to the front of the abdomen when the disturbance is in fact between the diaphragm and the base of the lung, many operations for gastric ulcer may be avoided and many lives saved by early resort to antituberculous treatment.

**6. Epidemic Poliomyelitis and Distemper of Dogs.**—R. H. Pierson has investigated a small epidemic of poliomyelitis which occurred among the Indians of fishing villages situated in central Alaska, near the town of Tanana on the Yukon River. The epidemic was not an extensive one. There were a few more than thirty cases in all. There were four deaths, three of which occurred in camps on the Yukon River and one at Tanana, Alaska. In five cases there was residual paralysis. The symptoms of poliomyelitis were in no way different from those which are usually described. Eleven of the cases came under observation of the army surgeons sta-

tioned at Fort Gibbon. The interesting features of this epidemic were associated with its mode of origin, its progress, and its decline. The epidemic among the human subjects was preceded by an epidemic of "distemper" among the dogs. The symptoms manifested by the dogs were the same as those shown by the human subjects. It is believed that the experience in this small epidemic will be of value in the study of other epidemics. The fact that the disease is more prevalent in rural communities where more dogs are kept is significant. The theory that the disease is common to dogs and human beings fits so well with the experience of epidemics which have taken place in different parts of the United States that it is well worth consideration. There is also the possibility that other domestic animals, as horses or cattle, may have the same disease. Its transmission by insects may not be confined to the horsefly. It may be carried from one individual to another by means of vermin. Many of the persons afflicted in this epidemic were manifested. It is quite probable that there are several modes of transmission. However that may be, this experience is sufficiently suggestive to be a warning to persons who live in rural communities to be careful to keep their houses screened and to see that their children do not become too intimate with young dogs which may have distemper.

7. **Trichinosis.**—J. M. Van Cott and W. Lintz conclude that trichinæ or their embryos are not found in the feces, hence these cannot be used for diagnostic purposes, nor are they a factor in the spread of the disease. Intestinal antiseptics are futile in this disease. Children either escape infection or when infected have the disease in a mild form because they eat only small amounts of the infected meat. A child is not endangered by nursing from an infected mother. For the first time living trichinæ have been demonstrated in the cerebrospinal fluid *in vivo*. In protracted and dubious cases of chronic muscular rheumatism it is advisable to examine a piece of muscle microscopically for trichinæ. Neither leucocytosis nor eosinophilia is an index of the severity of the disease. The trichinæ may wander into the tissues by boring through the fibrous connective tissues. It is a mistake to rely for diagnostic purposes on the finding of trichinæ in the blood, because such findings are rare. A new and simple method of staining trichinæ may be used. Salvarsan is useless, as was shown in the author's cases. Trichinosis should be made a reportable disease. A government microscopic inspection of meat for domestic use should be instituted.

8. **Prognostic Value of Slight or Transient Albuminuria.**—H. W. Cook concludes that in applicants over forty or forty-five it is of great importance to determine the presence or absence of a slight albuminuria. The slighter albuminurias are almost constantly overlooked by the average examiner. Apparently the only way to obtain this very vital information is to have the uranalysis made at the home office, although an improvement may be expected from the recommendation to the examiners of a more delicate and simpler test, such as Ulrich's test.

10. **Rupture of the Uterus Following Cesarean Section.**—L. I. Breitstein points out that a cesareanized woman who gives a history of an infection with a purulent vaginal discharge in the puerperium is a good candidate for rupture of uterus in one of her subsequent pregnancies. The mere fact that a cesareanized woman has delivered herself spontaneously is no reason for believing that she is free from the danger of rupture of the uterus with her future pregnancies. Rupture of a cesarean-section scar generally takes place in a scar resulting from improper wound-healing in the presence of infection. The implantation of the placenta on the site of the scar may so weaken the uterine tissue that it may rupture under the strain and stress of labor. He firmly believes that cesarean section should be limited to those cases in which it is strictly necessary. If there is any possible chance for the uterine wound to become infected some operative measure for sterilizing the patient should be employed. A cesareanized woman should be in a maternity hospital during the last month of her subsequent pregnancies so as to be under constant medical supervision.

9. Multiple Mesenteric Lipomata Causing Obstruction. S. Mort.

1. **The Operative Treatment of Fractures.**—E. W. Hey Groves states that the chief necessity of operative fixation (asepsis being assumed) is mechanical efficiency. The arguments for its necessity, derived from experimental evidence and extended to the condition of human fractures, may be summarized as follows: (1) In order to secure stable equilibrium at the site of repair; (2) to avoid postoperative sepsis, and to obviate the necessity of a second operation for the removal of foreign bodies; (3) to allow early massage and movements of the part without the restraints and restrictions of splints and bandages; (4) to prevent a bending of the newly healed bone when it is subjected to the body weight; there is only a minimum of callus laid down with fractures that have been operated upon, and the bone must be reinforced in strength for some time after the ordinary period of hospital treatment; (5) to obviate the disadvantages of delayed union of the bone, if such should occur; (6) to shorten the period of confinement to bed and retention of the case in the hospital. Soft iron wire is far superior to silver; it is much stronger than either bronze or silver. The second point of importance in using wire in bone surgery is that the fragments must be accurately restored to proper position, or at any rate to a stable equilibrium, before the wire is tightened. Therefore, for all these reasons the linear plating of fractures can only be regarded as a very temporary and insecure union of the bones, which can only succeed if (1) rapid vital union occurs; (2) splints are kept rigidly applied until union has taken place, and (3) that the part be one, such as the lower leg, which can be controlled and immobilized by splints.

2. **Errors in the Diagnosis and Treatment of Diseases of the Joints.**—A. P. Luff, in discussing the differential diagnosis of rheumatoid arthritis and gout, states that the confusion of these two diseases of the joints in their chronic forms is one of the commonest errors. Rheumatoid arthritis occurs most commonly in females; gout occurs mostly in males. Rheumatoid arthritis occurs more commonly among the poor and ill-nourished; gout mostly among the well-to-do and well-nourished. In rheumatoid arthritis there is very little pain at first. There is some aching in the joint, but it starts in a very insidious manner. It is this insidious character of the disease which is one of its bad features, for the patients do not seek advice until the affection is fairly advanced. Chronic rheumatic affections of the joints are generally accompanied by the formation of fibrous nodules, by the

development of extraarticular fibrous thickening, and not infrequently by the indication of valvular disease of the heart. Chronic fibrositis of the joints is most frequently met with in the knuckle and finger-joints of those engaged in hard manual labor, especially when associated with damp surroundings. In its early stages acute rheumatoid arthritis may very closely simulate acute rheumatism, but it may be distinguished from it by not reacting to treatment with salicylates. The disease usually commences in one joint, commonly one of the metacarpophalangeal articulations, and then rapidly spreads to other joints. The disease does not flit from joint to joint as in cases of acute rheumatism, and the joint swellings are persistent. The swelling is at first due to periarticular thickening rather than to effusion. Rapid muscular wasting, vasomotor troubles, and pigmentation occur. In the acute and subacute stages the temperature is raised, but as a rule is lower than in acute rheumatism. It is very common error to mistake a chronic villous synovitis, usually of one or both knees, for an arthritis. Chronic villous synovitis is a purely local condition and not a manifestation of a general disease. It is, unfortunately, described in some textbooks as "arthritis sicca." It usually occurs in the knee and is characterized by crepitus or creaking on movement and by pain and tenderness on use.

3. **Mitral Stenosis, Cardiac Thrombosis, Aortic Embolism, and Gangrene of Both Legs.**—H. E. Symes-Thompson reports a case presenting these conditions. The embolus measured 1¼ inches by ½ inch, and lodged at the bifurcation of the aorta, being too large to enter one of the common iliac arteries. The diameters of the common iliac and the common carotid arteries are ¼ inch and 1-3 inch respectively, and one usually regards an embolus which plugs one of these vessels, causing unilateral gangrene or sudden death, as a large embolus. The embolus in this case was therefore of exceptional dimensions. The diagnosis of mitral stenosis could not be established during life. There was some irregularity of the heart, but nothing else on which to found such a diagnosis could be made out, and there was no history of rheumatism. The thickening and tortuosity of the arteries suggested the possibility of syphilitic endarteritis, but the Wassermann test gave a negative result. The absence of sugar from the urine excluded diabetic gangrene. The patient, a man aged forty-seven, was admitted to the Great Northern Central Hospital February 5, 1913, complaining of discoloration of the legs accompanied by pain and loss of power. The illness had begun fourteen days previously, when pain came on suddenly in the legs. The pain was like pins and needles, was worse at night, and was marked by exacerbations and remissions. For five days he had ceased to be able to move his legs, and for one day he had noticed that his legs were blue. There had been a slight cough with a little expectoration since the illness began, and some shortness of breath for five days. Neither the past personal history nor the family history presented anything noteworthy. He had not been abroad; there was no history of rheumatism or syphilis.

4. **A New Method of Treating Chronic Colicystitis and Other Bacterial Infections.**—C. Russ has shown that certain bacteria suspended in an electrolyte through which a current passes aggregate at one or other of the electrodes during the passage of the current, and that the aggregation varies with the nature of the electrolyte and is probably due to affinity between the products of electrolysis and the bacteria. He subsequently found that electrification of the bacteria in certain solutions kills them. Since nearly all pathogenic bacteria move to the positive pole during electrolysis in sodium chloride solution, he thought they might be drawn out of ulcers and infected mucous membranes, etc., if a column of sodium chloride were superimposed on the diseased area and a current passed in the appropriate direction. If the positive pole were submerged in such a column of saline and the organisms drawn to it by the current, then, as the tissues became free from the bacteria, recovery would ensue. Incidentally also the bacteria would be killed during the process. In 1911 he commenced this study by applying the above mentioned ideas to chronic varicose ulcers of the legs. These are lesions which can be seen during treatment and are accessible and easily measured. These ulcers were of years', months', or weeks' duration, and were systematically measured as to their greatest diameters before each treatment. In the first case, to estimate the number of bacteria withdrawn by the process, a control was undertaken by planting a sample of the saline (stirred over the ulcer) before polarization, and counting the colonies which developed from 1 c.c. and ½ c.c. on agar plates, and also after polarization for ten minutes. The result, namely, no growth in the second set of plates, was a sharp reminder of the importance of the bacteriocidal effect of the treatment, in addition to any effect of drawing organisms out of the ulcers. The author next sought to determine whether the bacilli might not be withdrawn from the bladder in colicystitis. The technique employed by the author was as follows: The patient, who had voided his urine, reclined on a couch and a broad abdominal belt of layers of line was passed around the lower part of the trunk. This belt, which carried a core of metallic gauze, was wrung out with warm salt solution before application. Next a rubber catheter, furnished with several perforations round its eye, was passed into the bladder. The free end of this catheter was connected to 8 inches of glass tubing, which in turn was joined by a short length of rubber tubing to a glass funnel—everything being sterilized. A few ounces of the salt solution (2 per cent.) were next passed into the bladder, and the glass tubing, after disconnection from the funnel, was clamped a little above the level of the pelvis. A platinum wire 6 to 8 inches long was next passed down the catheter to within 2 inches of its eye. This wire was connected to the positive and the core of the helt to the negative pole of the electric battery. The fluid in the bladder rose and fell in the glass tubing with the respiratory movements and its movement served as an indicator that the catheter eye was within the vesical cavity. A constant current was now gradually turned on to a magnitude of 3 to 5 milliamperes and was allowed to run for twenty or thirty minutes. The method of treatment has a germicidal effect and also draws the organisms electrically from the affected parts.

2. Ante-Natal Hygiene: Its Influence Upon Infantile Mortality. A. Routh.
3. A Method of Producing Rapid and Fatal Intoxication with Bacterial Products, with Special Reference to the Cholera Vibrio. W. J. Penfold and H. Violle.
4. The Radical Cure of Procidentia Uteri in Elderly Women. M. Mamourian.

3. **Rapid and Fatal Intoxication with Bacterial Products.**—W. J. Penfold and H. Violle state that it has been shown by Hort and Penfold that sublethal doses of *B. typhosus* culture become lethal if injected in a large quantity of distilled water. They further showed that if the water be injected first into one vein and the sublethal dose of culture subsequently into another vein death resulted. The authors have found that distilled water sensitizes the body to many different bacterial cultures, including cholera culture. The sensitization is

equally well demonstrated by using cholera toxin after the actual organisms have been entirely removed. The intoxication with cholera toxin or culture in association with distilled water is acute, and death may be immediate. Acute death occurs if the cholera culture or toxin be given first and the distilled water afterward; the toxin may be given by channels other than the intravenous. The previous injection of concentrated saline has little effect on the type of intoxication, the authors discuss. The augmentation of toxic effect occurs with cultures of *Proteus vulgaris, B. pyocyaneus, B. dysenteriæ* (Shiga), *B. prodigiosus,* and also slightly with tuberculin, while it is not observed apparently with potassium cyanide or strychnine. The injection of lysed blood in small doses with sublethal doses of cholera culture produces acute death. The lysis of red cells is probably an important determining factor in the production of this effect.

4. **Radical Cure of Procidentia Uteri in Elderly Women.**—M. Mamourian notes that in dealing with the operative treatment Kelly states that "in those cases in which the vagina has been completely everted the lax outlet is resected with difficulty," and "there still exists a tendency of the uterus and the upper part of the vagina to bear down upon the repaired outlet." This tendency can be obviated by adopting an operative plan, on normal anatomical lines, comprising: (1) Reduction of the weight of the uterus proper; (2) removal of excessive cervical substances; (3) anteflexion of the uterus; (4) narrowing of the vaginal canal; (5) lengthening of the posterior vaginal wall; (6) restoration of the parallelism of the vagina to the conjugate of the pelvis; (7) restoration of the continuity of the cellular tissue around the new vagina; (8) repair of the pelvic diaphragm; (9) repair of the perineal body; (10) widening of the perineum and lessening the size of the pudendal orifice. All the above requirements are fulfilled by curettage, amputation of the cervix and anterior colporrhaphy.

**Cause of Variola.**—Rabinowitsch of Charkow claims precedence over all contemporaries in being the first to make a pure culture of an individual germ—a streptodiplococcus—which he alleges to be the actual cause of variola. He has studied this germ for years, and in 1910 states that he caused variola in the calf. The best that others could do was to demonstrate structures or tissues which contained the unknown cause. The reaction produced resembled that described by Fornet. The culture cannot pass through a bacteria-tight filter, so that all phenomena (Guarnieri reaction, etc.) produced by filtrates cannot represent the cause of the disease. These filtrates, he says, are all sterile, so that the reaction is produced by toxic products. Much information is given as to the biological qualities of the germs. The material studied came from the local smallpox epidemic of 1909. The streptodiplococcus was universally present, as a very small microorganism, staining with Giemsa. Of great importance is the fact that these finds were sometimes seen in cows' lymph. As a result of his early work he published a brochure in 1910 on the differences between variola and vaccinia, in which these discoveries were announced. He claims that his work is ignored by Fornet and other contemporaries who are seeking to solve the riddle of variola. Naturally there can be no identity between his streptodiplococcus and corpuscular bodies like the "microsoma variolæ," which simply include the former. So close does the actual cause adhere to inclusive bodies that Fornet expressed doubt as to whether the actual germ could ever be isolated and grown. Inoculation of the calf has been performed, as already stated, a vaccine like pustule being the result. But in the case of small laboratory animals the same operation caused typical pocks, rabbits and rats showing a peculiar susceptibility with the old technique of vaccination. Whether these pustules represent variola or a vaccinoid condition has not yet been shown.

**Normalization of the Upper Jaw in Complete Cleft Palate.**—Numann states that he devised a procedure for this purpose while quite unaware of Brophy's method. His ideal was that of the American—to improve existing conditions. After a description of the technique of the two methods he sums up as follows: Normalization of the upper jaw is the only procedure justifiable in complete fissure of the jaw. The wires of Brophy and clamps of the author, as used in effecting this condition, are not necessary in simple cleft palate. The author's clamp is of metal, and invests the jaw above the level of the dental germs. The treatment is highly technical, varying with the case, and no illustrations accompanying the text. It is kept up until the jaw is rendered normal. No cases are given, and the general reader obtains but a vague idea of the method.

*February* 12, 1914.

**Hostile Criticism of Abderhalden's Serodiagnosis of Pregnancy.**—Michaelis and Lagermarck, who have kept in close touch with this subject since its outset, and who have followed zealously all the details prescribed by its discoverer, now announce that chiefly as a result of control investigations the serum of the gravida differs in nowise from that of nongravida and of men; that is to say that the differences, should such be present, cannot be utilized for practical purposes. Many kinds of serum may exert a minimal digestive action on boiled placenta substance; but there is no suggestion of specificity in connection with pregnancy. But there is always present a factor of importance in the techniques of the dialysis procedure which alone would invalidate all of the results thereby obtained. The phenomenon of "albumin leakage," supposed to indicate permeability of the hull, by Abderhalden, may be interpreted in a different manner. In conclusion the authors see no evidence of the existence of a specific ferment in the blood of the gravida which tends to antagonize the existence of placental material into that fluid.

**Abderhalden's Dialysis Procedure in Psychiatry.**—Kastan follows the preceding article by a companion study. In summing up his article he states that two subjects have chiefly been investigated, viz., the dysfunction of the thyroid and genital glands. The former is expressed in myxedema, the latter in nuclein metabolism, originally effected in the thymus, and at puberty passing into the genital glands. This transfer touches closely on dementia præcox. We know that in thymectomized animals the nucleins in the ganglion cells seem to cause an increased excitability, involving both the motor nerve symptoms and the psyche. Calcium salts tend to antagonize the action of nucleins, so that in self-defence the ganglion cells try to obtain lime from the body at large or the food. Meanwhile the nucleins change the fat of the cells to lipoids. So much lime becomes used up that the cells become lime poor. These changes mark the development of dementia præcox. The damage to the cells is believed to lead to the absorption by the blood of substances which cause the formation of defensive ferments. As far as we know the said substances comprise fats and sugars, which split off alcohol in the blood. We might infer that the rationale of Korsakoff's psychosis is not entirely unlike the cause of dementia præcox.

# Insurance Medicine.

## SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

### THE WASSERMAN REACTION

THERE is a widespread misconception in regard to the actual utility of the Wassermann test, judging from the communications received in regard to the use of this method, some physicians giving the impression through their written statements that they regard it as a means for determining whether or not the applicant has been thoroughly cured of syphilis. The complement fixation reaction, of which the Wassermann and Noguchi methods are the modifications most commonly applied, serves most excellently as a control or guide in the treatment and management of syphilis. In the light of present knowledge, sailing a ship without a rudder would be as aimless a procedure as the attempt to treat a case of syphilis intelligently without the control provided by the employment of the Wassermann test. When, however, the reactions become negative and remain so for months or years the proof afforded by the simple Wassermann test that the patient is cured is only about 50 per cent. good, as positive reactions are obtained in the remaining 50 per cent. of cases by other methods, such as the provocative Wassermann or the luetin test in patients who had long been considered cured.

The provocative Wassermann test, already referred to in these columns in a previous number, consists of the intravenous injection of a dose of salvarsan, followed in about five days by the regular Wassermann test. It would be better to make several provocative Wassermanns between one and fourteen days after giving the salvarsan. The salvarsan provokes any remaining spirochetes into violent energy, with the consequent production of toxins entering into the process which leads to a positive reaction. Before an application is stamped with approval at the home office a year should have elapsed since the last administration of treatment, and there should have been three or four simple negative Wassermann tests at regular intervals, followed by a negative provocative Wassermann at the end of the year. The luetin test, while of undoubted value, has not become popular.

It is highly important that the limitations of the Wassermann test, as well as its uses, should be recognized by the medical profession and the laity. Cures are believed to have followed a single injection of salvarsan. In the majority of cases, however, the administration of one or two doses of salvarsan may be followed by several negative Wassermann tests, but if the treatment is allowed to rest at this stage the probability is strong that there will be a relapse or the lodging of some spirochetes in inaccessible centers, where they will sooner or later flare up and do irreparable damage. This point must be recognized as one of vast practical importance, and to shut our eyes to it would be folly. It has been stated, and with good reason, that syphilis is one of the poorest treated diseases, either because the attending physician is too soon satisfied that a cure has been accomplished, or the patient fails to remain long enough under observation. A medical director, then, should regard the statement that the Wassermann test has given a negative reaction after a short or even long course of treatment merely as an indication that the patient is being cared for with the proper amount of precaution, and insist upon a more certain means of diagnosis before giving his final approval to the application.

A medical officer ought to assure himself, moreover, even when a provocative Wassermann has been applied with negative results, that the test was conducted by an unquestionably competent serologist. Serum diagnosis is indefinite, and a proper reading of the results cannot be accomplished unless the operator has had wide experience. Serologists themselves differ at times in interpreting the reaction obtained in the same specimen of blood, and it is not difficult to imagine that small reliance can be placed on the outcome of this difficult and complicated process in comparatively untrained hands. Self-styled serologists, indeed, are springing up in all parts of the country.

While skill and experience are demanded for properly interpreting the results of the complement fixation reaction, further difficulty arises from the fact that the supply of the different complicated ingredients required for the procedure must be conveniently at hand and carefully prepared. The antigen, for instance, must not be over twenty-four to forty-eight hours old. Moreover, the strength of the complement, amboceptor and antigen must be determined on the day of each test by titration, and correctly standardized. Serum diagnosis is an invaluable measure, but it is capable of misleading us into seriously wrong conclusions and a false sense of safety. The medical officers of life insurance companies will find it a priceless contribution to the scientific selection of risks, but only when careful discrimination is observed in accepting the results.

---

**Comparison Between Male and Female Risks.**—Dr. H. A. Baker, Medical Director Pittsburgh Life & Trust Company, says that by comparison with the causes of death among men it is seen that the percentage of deaths from the following causes is greater among men than among women: Typhoid fever, appendicitis, cirrhosis of liver, suicide and accident, while there is a greater proportion from cancer and other malignant tumors among women than among men. After a review of much of the insurance evidence on the subject, Baker concludes that from a physical standpoint female risks are at least equal in logevity to male risks; but that the element of moral hazard is, however, greatly accentuated among female risks, which results in an increased mortality and renders their selection correspondingly more difficult.—Medical Section, American Life Convetnion.

**Examination of Women Applicants.**—Dr. W. F. Blackford, Medical Director Commonwealth Life, Louisville, Ky., recognizing that women are as insurable as men under proper restrictions: namely, the removal of the speculative feature, thinks that the medical directors have a problem to face that is even greater than the question of the insurability of women. How can the agents and examiners be assisted in securing proper applications and competent and thorough examinations of female applicants? When this question is solved he considers that the medical department will have added a great field for agents to work in which will give manifold results in handling female insurance, protecting the companies and at the same time obtaining the best results.—Medical Section, American Life Convention.

# Book Reviews.

TRANSACTIONS OF THE AMERICAN SURGICAL ASSOCIATION. Vol. XXXI. Edited by ARCHIBALD MACLAREN, M.D., Recorder of the Association. Philadelphia: William J. Dornan, 1913.

THIS volume, like its predecessors, contains lists of the officers of the association, the list of the presidents since its organization in 1880, the list of fellows, short biographical sketches of fellows recently deceased, and the papers read at the annual meeting held at Washington May 6, 7, and 8. There are 36 papers, which, taken together, cover a wide range of surgical subjects. There is also the inaugural address of the president, Dr. Charles A. Powers, and the report of the committee on fractures. The association lost by death a number of prominent fellows during the previous year, and biographical sketches are given of Lord Lister, who was an honorary fellow, and Drs. John S. Billings, Charles W. Oviatt, Beverly MacMonagle, Orville Horwitz, Alexander H. Ferguson, and Algernon T. Bristow. The individual papers have already been published in leading medical and surgical journals, hence it is unnecessary as well as unfair to single out special articles for comment at this time. Suffice it to say that the high standard of excellence which we have become accustomed to expect in the contributions read before this association has been more than maintained.

A MANUAL OF SURGICAL TREATMENT. By Sir W. WATSON CHEYNE, Bart., C.B., D.Sc., LL.D., F.R.C.S., F.R.S.; Hon. Surgeon in Ordinary to H. M. the King; Senior Surgeon to King's College Hospital; and F. F. BURGHARD, M.S. (London), F.R.C.S.; Surgeon to King's College Hospital, and Consulting Surgeon to The Children's Hospital, Paddington Green. New edition entirely revised and largely rewritten with the assistance of T. P. LEGG, M.S. (London), F.R.C.S.; Surgeon to the Royal Free Hospital; Assistant Surgeon to King's College Hospital; and ARTHUR EDMUNDS, M.S. (London), F.R.C.S.; Surgeon to the Great Northern Central Hospital; Assistant Surgeon to King's College Hospital. In five volumes. Vol. V. The Treatment of the Surgical Affections of the Pancreas, Liver, and Spleen; the Neck, the Breast, and Thorax, and the Genitourinary Organs. Price $6.00. Philadelphia and New York: Lea & Febiger, 1913.

THE present volume, which brings to a conclusion this valuable work, treats of the surgical affections of the pancreas, liver, spleen, neck, larynx, breast, thorax, and genitourinary organs. The successive volumes have followed each other with a promptness which is commendable and unusual, thus making it possible for the doctor to secure an authoritative work on surgical treatment which is up to date throughout. Generally, in a work in several volumes, the earlier ones of the series are out of date by the time the later ones are in the hands of the readers; the present case is a notable exception to this rule.

OPERATIVE SURGERY. For Students and Practitioners. By JOHN J. MCGRATH, M.D., Clinical Professor of Surgery, Fordham University; Professor of Operative Surgery, New York Post-Graduate Medical School; Consulting Surgeon to the People's Hospital; Visiting Surgeon to the Harlem and New York Foundling Hospitals; Fellow of the New York Academy of Medicine; Member of the American Medical Association. Fourth Revised and Enlarged Edition, with 364 illustrations, including full-page color and halftone. Cloth; 838 pages; price $6.00 net. Philadelphia: F. A. Davis Company, 1913.

THE first edition of this book was published in 1902 under the title "Surgical Anatomy and Operative Surgery," and the subject matter was arranged in accordance with the plan followed in the author's courses in operative surgery at the New York Post-Graduate Medical School. It seems unfortunate that the author has dropped the first part of the title, for the remarks on surgical anatomy have not only been retained, but have been amplified in certain cases, and form a somewhat unique and truly valuable feature. The original plan of presenting the subject has suffered little change, the general headings coming in practically the same order as in previous editions; but the great advances made in surgery during the last few years have necessitated the rewriting of many portions and the addition of much new matter.

McGrath has kept the textbook idea in mind in bringing the book up to date and the result is eminently satisfactory; for thus being obliged to keep the work within reasonable space limits, he has chosen what seem to him the best of the most recent additions in the way of operations and operative technique, incorporating those procedures of proven merit, and has made no attempt to include all the latest fads, many of which will soon be discarded. There are altogether too many books on this subject which are clearly hardly more than compilations, and it is a pleasure to note that in this instance we are dealing with a book that was written for a specific purpose and where the author's personality is impressed upon nearly every page.

Inevitably certain errors and omissions may be found in a work of this kind. Here we find no mention, in the index at least, of operations upon the pituitary body, the employment of fat-fascia flaps in arthroplasty, Foerster's operation for resection of posterior nerve roots, or some others just now receiving considerable attention. Generally speaking, however, the field of operative surgery is very well covered and the book certainly deserves continued popularity.

AN INTRODUCTION TO THE HISTORY OF MEDICINE, with Medical Chronology, Biographical Data, and Test Questions. By FIELDING H. GARRISON, A.B., M.D., Principal Assistant Librarian, Surgeon General's Office, Washington, D. C. Cloth; $6.00 net; half morocco $7.50 net. Philadelphia and London: W. B. Saunders Company, 1913.

ALTHOUGH this book is modestly styled an "introduction," it is really a finished product and is a clear and succinct account of the development of human medicine from its inception to the present moment. The author starts his work most auspiciously by pointing out that the beginnings of medicine, like those of language and the industrial arts, were practically identical in the various tribes of primitive man. He then proceeds to develop his main thesis, "that the folk-ways of medicine are inevitably the same and independent of time, place, and circumstance." To this postulate he adds the equally important axiom that the primitive mind is essentially "discontinuous" (as Rowland scornfully asserts of the "ordinary cultivated or legal mind"). These two postulates being granted, the halting development of medicine, which might be styled "steady by jerks," is largely explained.

No small part of the charm of the book is due to the apt and often droll touches of character painting, which the author indulges in. It is delicious when he speaks of that solemn humbug, Sir Kenelm Digby, as an Übermensch (page 2217) and then goes on to relate that practically everybody, even the self-constituted exposer of all deception, Paracelsus, fully believed in the "sympathetic powder" delusion, or pretended that he did. It is not, however, in the character touches alone that the master hand of the medical historian is shown. In speaking of the system-makers of the 18th century, Garrison says (p. 240): "We see the great theorists of the time as Emerson has described the gods, each sitting apart in his own sphere, 'beckoning up to their thrones.' Yet somehow, Hippocrates and Sydenham, Vesalius and Harvey, Celsus and Paré, seem nearer and more accessible to moderns than Stahl or Barthez, Borden or Boerhaave, Brown or Reil." He might have added just as the great peaks of a mountain range seem nearer to the observer than the intervening foothills.

Our author never loses sight for a moment of his main thesis, nor forgets that he is writing a compact and well balanced history of perhaps the most potent factor in the development of the human race, except religion. He has produced a book which with its excellent indices, medical chronology, and test questions should be the *vade mecum* of every physician whose ideas are above the level of the tradesman's, which will delight the man of literary taste, and instruct and amuse even the casual reader. The pictures are interesting and materially add to the reader's pleasure.

The work is accurate, painstaking, and fair. It comes at an especially opportune time and represents a great amount of careful preparation. Probably its most valuable feature is that it demonstrates beyond all cavil that in spite of setbacks, mistakes, and the pernicious influence of numberless "systems" and delusions, medicine has advanced in every department until the greatly desired day of preventive medicine, the *summum bonum* of human good, is even now dawning. And, lastly, it relieves America of the aspersion cast upon us by the learned Dr. Baas and others, that we have yet to produce a good history of medicine.

Principes d'Anacousie (Reëducation Auditine). Par A. Zundbupguet. Preface du Professeur C.-M. Gariel. Paris: A. Maloine, 1913.

The author recites the history of auditory reëducation, and says that it has made great strides. Much space is given up to the electrophonoid, an instrument constructed like the human voice. It has three registers corresponding to singing bass, baritone, and tenor or soprano. Each register can produce a series of sounds extending over an octave. By this apparatus the deaf are taught to concentrate, thus increasing auditory function, drying up old discharge, regenerating tissues, and bringing about favorable vasomotor changes.

It is of use in paracusis Willisi, juvenile sclerosis, chronic adhesive processes, and arteriosclerosis of aural vessels—in fact, in all cases where Costi's organ is not entirely destroyed. Contraindications are sudden deafness of syphilitic origin, cerebrospinal meningitis, and toxic infectious labyrinthitis. There is hope of improvement even when the loud voice is heard only *ad concham*, and 75 per cent. of the deaf who come to specialists may be relieved by the electrophonoid. If after fifteen seances there is no improvement further treatment is useless, but "such contingency is very rare." The author evidently is sincere in believing that he has found a therapeutic means of the greatest value to otology.

Malaria, Etiology, Pathology, Diagnosis, Prophylaxis, and Treatment. By Graham E. Henson, M.D., Member American Medical Association, Florida Medical Medical Association, Southern Medical Association, American Society of Tropical Medicine, Medical Reserve Corps, United States Army (non-active list). With an introduction by Charles C. Bass, M.D., Professor of Experimental Medicine, Medical Department Tulane University, New Orleans. Twenty-seven illustrations in 190 pages. Price $2.50. St. Louis: C. V. Mosby Company, 1913.

This book is written for the general practitioner by a man whose experience and research in this disease for many years in one of the most intensely malarious sections of the United States enables him to review the subject from the most practical standpoint. The development of the South has been held in check mainly by three diseases, yellow fever, hookworm disease and malaria, the latter perhaps taking greater toll than the others. Malaria continues unchecked for lack of sufficient knowledge on a subject as simple as either yellow fever or hookworm disease. There is little doubt that the eradication of malaria is the most serious problem that confronts the sanitarian in all tropical and subtropical countries. If proper attention is paid to diagnostic methods there is probably no disease more easily diagnosticated, and if treatment is properly instituted there is probably none that responds so surely, as shown by the wonderful results obtained by Colonel W. C. Gorgas. The position and experience of the author lend special weight to his words and the book is recommended to all who are interested in malaria and its eradication.

The Psychopathology of Hysteria. By Charles D. Fox, M.D. Price $2.00 net. Boston: Richard D. Badger, 1913.

But few books have as yet been published in English in which hysteria as a whole has been treated on the basis of the results of recent psychopathological researches. This one would appear to be one of the best of this kind. The subject is treated in a way both clear and understandable. Each and every pathological condition or manifestation of hysteria, the author teaches, is the logical outcome of a train of morbid subconscious ideation which, in turn, was the result of some external stimulus. The author's definition in part describes hysteria as a psychoneurosis in a neuropath with vicious environment, dependent upon disintegration of the personality and characterized by symptoms originating from the morbid control of the body by subconscious states. These symptoms, he says, can be shown to be but exaggerations or perversions of the normal; while many of the phenomena and "accidents" of the disease result from the increased suggestibility present. The theories of Freud and Janet have been drawn upon extensively in the composition of the book. Among the etiological factors of hysteria discussed are heredity, environment, faulty education, age, sex, social factors, occupation, race and climate, as predisposing factors; and, as exciting causes, acute psychic insults, chronic mental stresses, toxemia, and psychic contagion are mentioned. There are chapters on disturbances of sensory perception, visceral and circulatory derangements, psychomotor disorders, psycholepsy, alterations of consciousness, multiple personality, hysteric temperament, suggestibility, and diagnosis and treatment. The chapter on treatment concludes as follows: "The most logical and effective form of therapeusis includes the discovery, by means of some psychoanalytic method, of the causal submerged complexes; synthesis of these with consciousness; and, through the agency of psychic re-education, the removal of psychopathic tendencies."

American Red Cross Text-Book on Elementary Hygiene and Home Care of Sick. By Jane A. Delano, R.N., Chairman of the National Committee, Red Cross Nursing Service; Late Superintendent of the Nurse Corps, U. S. A.; of the Training School for Nurses, Bellevue Hospital, New York, and of the Training School for Nurses, Hospital of the University of Pennsylvania, Philadelphia, and Isabelle McIsaac, R.N., Member of the National Committee, Red Cross Nursing Service; Superintendent of the Nurse Corps, U. S. A.; Late Superintendent Illinois Training School for Nurses, Chicago; Author of "Primary Nursing Technique," "Hygiene for Nurses," "Bacteriology for Nurses." Prepared for and Indorsed by the American Red Cross. Price $1.00. Philadelphia: P. Blakiston's Son & Co., 1913.

One-half of this little text-book is given up to such practical subjects as lead to the prevention of disease. This study of the elementary household hygiene in connection with the person, the household and the community shows that in the estimation of its authors prevention is of the utmost importance. Almost every chapter is introduced by a few suggestions for simple demonstration, and in a few instances a vocabulary. This holds the interest and makes the subject matter more intelligible.

Clinical Disorders of the Heartbeat. A Handbook for Practitioners and Students. By Thomas Lewis, M.D., D.Sc., F.R.C.P., Assistant Physician and Lecturer in Cardiac Pathology, University College Hospital; Physician to Out-Patients, City of London Hospital for Diseases of the Chest. London: Shaw & Sons, 1913.

Dr. James Mackenzie has pointed the way to new conceptions of certain forms of heart disease, and Dr. Lewis, himself an originator of new views in the same direction, has been an earnest follower of Dr. Mackenzie. As he said in the first edition of his book, a new chapter has been added to our knowledge of the mechanism of the heartbeat during recent years—knowledge gathered by the employment of precise graphic methods. The object of the book is to afford medical men a means of gaining information of the new facts and conclusions which are of chief service at the bedside. In the present edition the main body of the book is in its original form; the new part consists chiefly of the addition of a short chapter upon auricular flutter. The work is calculated to be of great use to the busy practitioner who can learn from it enough to understand the salient facts of the mechanism of the heart.

Researches on Rheumatism. By F. J. Poynton, M.D., London, Fellow of the Royal College of Physicians of London, Vice-Dean of the University College Hospital Medical School, Senior Physician to Out-Patients at University College Hospital, London, and at the Hospital for Sick Children, Great Ormond Street; Physician in Charge of the Children's Ward, University College Hospital; and Alexander Paine, M.D. (State Medicine), London; D.P.H., Eng., Director of the Cancer Hospital Research Institute, London. Price $5.00. New York. Macmillan Co., 1914.

In this volume there are collected the chief papers bearing upon the research of the subject of rheumatism which has extended over a period of 15 years. Some of the papers were written before the authors demonstrated what they believe to be the cause of the disease; others elucidate the nature and action of that cause; others, again, extend the main theses dealing with allied conditions. At the conclusion of the volume the bearing of these investigations upon clinical medicine and public health is considered in a special article. Collaborators are Drs. V. Shaw, Gordon Homes, G. F. Still, D. B. Lees. The book consists of three main divisions: (1) Papers written before the isolation of the *Diplococcus rheumaticus;* (2) papers written after the isolation of this organism; (3) a study of acute rheumatism based upon the results of the previous researches.

# Society Reports.

## MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

*Stated Meeting, Held January 26, 1914.*

THE PRESIDENT, DR. T. PASSMORE BERENS, IN THE CHAIR.

**Inaugural Address of the President Elect.**—Dr. T. PASSMORE BERENS made this address. He expressed the belief that the burden of responsibility which his office entailed would be greatly lessened by the hearty co-operation of each and every member of the society, the Comitia Minora, the board of censors, and the various committees, as well as by the counsel, the secretary, Dr. John Van Doren Young, and the treasurer, Dr. Charles H. Richardson. The speaker recalled that November 14 of this year would be the 120th birthday of the society. In 1806 their membership was 371, and every doctor in the city was a member of the society by virtue of his right to practise medicine. To-day its membership was 2,492; it was the largest local medical society on the continent, and each applicant must prove his fitness for the privilege of becoming a member. There were still 2,700 physicians eligible to election who would give strength to their cause. The 3,000 mark should be passed before the meeting of the State Medical Society in April. This would be the 108th meeting of the State society and its first annual meeting in this city, and they should bear in mind that this session was at their invitation, and therefore they should demonstrate their interest and prove their hospitality by a large attendance at the scientific sessions as well as at the dinner. The aims and objects of the Medical Society of the County of New York had been the same through the many years of its existence, the protection of the health of the community, the elevation of the standard of the profession, and the elimination of the quack and the charlatan. For one hundred and twenty years they had struggled for these aims. The benefit of membership were now greater than ever before, but could they not be augmented if the vast amount of clinical material in their hospitals were rendered available to all members? This was a tentative suggestion made in the hope that at no distant date it would become a fact. The work of the committees of this society was laborious and varied. The maintenance of discipline and the application of the interpretation of the principles of ethics was frequently most disagreeable. The question which had perplexed them more than any other was the determination of certain principles of ethics, violations of which were being brought before them continually, and upon which action was demanded by those making the specific complaint. Dr. Berens said he referred particularly to the growing tendency to instruct the laity in the public press, and incidentally to bring into prominence the personality and practices of the individual physician. These articles varied from those with an obvious intent to exploit and advertise the author under a thinly concealed pretense at interview, and those of a purely altruistic nature where the personality of the author was less apparent. It was to call the attention of the society to this state of affairs that Dr. Sondern had been directed by the Comitia Minora to prepare the report which he would offer to-night. If they were wrong in considering the newspaper articles which he would mention as offensive against the best interests of the profession they would remodel their ideas relative to the standard of ethics; if they were right, it was to be hoped that this method of calling to the attention of those who had offended would work the improvement desired by them all. In closing, Dr. Berens begged that his administration would be accorded the same hearty support that had been granted that of his distinguished predecessor, Dr. Wells.

**Publicity in the Lay Press by Members of the Society.**—Dr. FREDERIC E. SONDERN presented this report as the representative of the board of censors. He stated that the board of censors had observed with regret the rapidly increasing number of publications in the lay press concerning the professional activities of many prominent members of this society. It had been found that these articles appeared in the daily newspapers, particularly in the Sunday editions, in the weekly illustrated papers, and in the monthly magazines. Some were written by the physician himself and some by a lay author whose name was mentioned, but in the majority of instances it was difficult to decide if the article was written by the physician or by someone else. The majority of these publications had the physician's pictures, and some were profusely illustrated, showing the physician at work in his office, laboratory, clinic, or hospital. Examination of these articles showed that they might be divided into several groups: (1) Those designed for the publicity of an institution, calling attention to the achievements therein and the advantages it enjoyed, and while the success of one or more prominent workers was often unfortunately conspicuously displayed, the ostensible purpose of the communication was to help the institution. (2) Those concerning modes of treatment, and while the primary object seemed to be to satisfy the public desire for information there was unfortunate prominence given to one or more physicians whose pictures usually appeared in the article and whose personal success with the remedy in question was exploited. (3) Those concerning one man, detailing his origin, his education, his opportunities, his achievements, and his success, and while such publicity might be considered a suitable recognition of arduous labor well performed, there was usually something said in the article which reduced it from a testimonial to a solicitation. Books were written by physicians containing advice on matters of hygiene, sex talks, and a host of other subjects intended to improve the public health, and these were sold or distributed gratuitously. Again there were many instances in which philanthropy was but a cloak for personal aggrandizement. Many of the lectures delivered by physicians to lay audiences belonged under this head. According to the principles of medical ethics, enacted by those ripe in experience and whose modest personal lives commanded their respect, this was all advertising matter. It was not their intention to convey the idea that every article such as they were considering was an advertisement written by the man described for the purpose of increasing practice. There were, doubtless, some which appeared without the knowledge or consent of the man described. There were others, particularly those descriptive of institutions, in which the worker in his zeal to do justice to the great work accomplished therein unwittingly appeared in a prominent manner. But most of these were advertisements just the same as those in which a physician described his personal ability in the practice of medicine or of a specialty, and in the language of their code of ethics, they defied the traditions and lowered the tone of the profession. The excuse that such articles were in part copied from the medical journals was not valid, as all medical journals were copyrighted, and such reprinting could be prevented if desired. The Comitia Minora was not alone in this complaint. The accusation had come from other sources that the so-called noble profession was at present characterized by a spirit of commercialism and the crudest egotism. The German and English journals also showed evidence of the growing evil of publicity in the lay press. Saunby in his "Medical Ethics," London, 1907, stated that the publication of biographical sketches and other laudatory notices of medical men in the lay press was to be deprecated, and practitioners should not consent to this sort of publication. They should not sanction quotation of extracts from their published medical writings. It was not the duty or the intention of the board of censors to suggest action in this matter; but it was their duty as the result of complaint, to bring it to the attention of this society, with the comment that they deplored its occurrence and were unable to stop what was believed in the main to be self-laudation rather than public health education. The public demanded information on the progress in medical science and had a right to do so, but what was printed should be the substantiated truth and not the possibly immature ideas of an enthusiast who might awaken false hope and by the unsuccessful outcome of his efforts lower the confidence of the public in the profession. This society had undertaken the work of public health education along other lines, and if it saw fit might also instruct the public through the medium of the press far more efficiently than was now done by the self-laudatory efforts which were the subject of this communication. The Nestors of their profession of twenty years ago, whose prominence, accomplishments, and successes were as great as those of any to-day, confined their pictures to this building and the family album and their professional opinions to the medical press. There were among them

to-day men of equal prominence whose pictures could not be purchased by the newspapers and whose opinions expressed in the medical journals never appeared in the newspapers. These were the men who were responsible for the respect of the community enjoyed by the medical profession as a whole.

**Early Recognition and Medical Treatment of Gastric and Duodenal Ulcer.**—Dr. WILLIAM VAN VALZAH HAYES presented this communication. He said that in view of the great prevalence of gastric and duodenal ulcer and their troublesome sequelæ, it was of the utmost importance that the medical profession should seek to make a diagnosis at the earliest possible moment, or to go a step further and ascertain what were the factors predisposing to ulcer and to correct them before greater damage was done. It was the cases not giving the definite cardinal symptoms that required special attention. It was essential that a painstaking history should be taken covering the following points: (1) Duration of trouble. (2) Periodicity of attacks. (3) Pain, as regards character, time, location; whether helped by belching, spontaneous or induced vomiting, taking of food or alkalis, and the effect of acid or irritant food or cold drinks. (4) Appetite, whether increased or diminished. (5) Regurgitation of acid or liquid food. (6) Constipation. In many cases there might be only fulness or discomfort with possibly moderate prolongation of digestion or acidity with constipation and the diagnosis must be made by the various tests and the *x*-ray independently of the history. The objective signs which helped to reveal the presence of ulcer were: (1) A tender point a few centimeters in diameter sharply defined and more or less constant in a given case. This might be just below the ensiform cartilage or in the region of the solar plexus. At times it was found to be over the actual site of the ulcer, but this was not always true and other evidence must be sought for definite localization. The *x*-ray workers emphasized the importance of tenderness over the stomach or duodenum moving with respiration. (2) A dorsal point of tenderness which might be found to the left of the tenth, eleventh, or twelfth dorsal vertebra, sometimes also on the right side or at a higher level. (3) In long-standing cases there might be resistance due to adhesions or a small palpable tumor or ridge if the edges of the ulcer were markedly indurated. As a rule in cases of recent hemorrhage or suspected acute ulcer the stomach tube should not be used. When admissible the employment of test meals was highly helpful. It was important that a stomach tube with closed end and depressed eyes should be used, and all hard straining avoided. When the tube could not be used the following method of examination might give valuable aid in determining whether the digestion was prolonged and the acidity excessive: A test meal of two soft boiled eggs, one French roll with butter, and one glass of water was given in the morning. Three and a half or four hours later examination of the abdomen was made, the patient reclining with head and shoulders moderately elevated. If succussion was readily and continuously elicited it showed prolonged digestion with myasthenia. If succussion was absent, but after separating a pouch of the stomach by gentle pressure a gurgling was produced as the patient exhaled, prolongation of digestion existed, probably due to hypersecretion or pyloric spasm. One-half dram of sodium bicarbonate was now given in two ounces of water; if it caused a notable increase in gastric tympany the presence of free acid, almost certainly hydrochloric, was shown. This test should not be used when acute ulcer was known to exist, though it was practically without danger. Special importance attached to the presence of occult blood in the gastric contents or the stools, provided other sources of bleeding could be excluded with reasonable certainty. The guiac test for occult blood gave satisfactory results. The thread test according to the Einhorn method slightly modified was used. When the thread had been retained over night, normally the lower end of the thread if it had entered the duodenum was green or yellow, its upper portion remaining white. If, however, a blood stain appeared, and one or two subsequent tests showed the stain at the same distance from the teeth, it was clear evidence of a definite break in the continuity of the mucous membrance, and, taken in conjunction with other evidence, was most helpful in the diagnosis of ulcer, particularly those situated at the pylorus and along the lesser curvature, where it was said 85 per cent. of chronic and a large percentage of acute ulcers were found. With duodenal ulcers occurring largely along the upper portion of the cap it was probable that the thread often failed to touch the ulcer surface. Röntgen examination might show the following conditions suggestive of gastric ulcer: Interruption of the normal peristalsis at a definite point along the stomach margin. Incisure of the greater curvature, due to spasmodic contraction opposite the seat of the ulcer on or near the lesser curvature. Slight irregularity of outline of stomach near the pylorus. Pylorospasm with gastric delay. In ulcer of long standing, where perforation, adhesions, or contractions had occurred, there might be found evidence of diverticula, fixations, marked flattening of the lesser curvature, hour glass deformity, or pyloric stenosis. Conditions suggestive of duodenal ulcer were: 1. Hypermotility of the stomach and duodenum associated with a vacant area in the duodenum which remained fixed in all examinations. 2. Spastic indrawing high up near the greater curvature of the stomach, associated with tenderness over the duodenum and increased by manipulation of the duodenum. 3. Deformity of the cap. In the absence of acute or chronic perforation repeated hemorrhage, progressive anemia, obstructive conditions, and suspicion of cancer, every case should receive the benefit of at least six months' careful medical treatment and observation before having recourse to surgery. As a rule the following principles should be insisted upon: Rest in bed for a period of four weeks with freedom from responsibility and care. This rest should be absolute so long as there was any sign of occult blood in the stools. An icebag should be kept on the epigastrium most of the time if hemorrhage had occurred and this treatment continued until occult blood no longer appeared. Later a warm compress was kept on the stomach. Abstinence from food or liquid by stomach from two to four days was desirable if there had been marked hemorrhage or great sensitiveness over the stomach or duodenum, provided, of course, the patient was strong enough to justify the partial starvation. During this period rectal alimentation might be employed. During the first twenty-four hours saline solution might be administered by the Murphy drip method, and later the following enemata: Four to six ounces of pancreatinized milk, one-half ounce glucose, and ten to fifteen grains of salt; or normal saline solution one pint and glucose one-half ounce. The essayist gave a modified Lenhertz diet list for the first ten days which by the tenth day represented a caloric value of 1,900 calories. At the end of two weeks the diet might include soft boiled eggs, milk soups, cornstarch, custard, farina, and arrowroot. The writer preferred in general a diet moderate in proteids and very low in extractives. Bland fats diminished the acidity and had high caloric value. Cohnheim advocated olive oil, a wineglassful in the morning and two dessertspoonfuls one-half hour before dinner and supper to be continued for weeks or months. In feeding by the duodenal tube the writer used a slight modification of the Einhorn method. Duodenal feeding was too new to justify enthusiastic statements, but it seemed reasonably certain that it constituted a valuable addition to the established methods of treatment. The medicines of value in ulcer were the following: (1) Bismuth subcarbonate suspended in water in doses of one-half to one ounce three times daily one-half to one hour before taking food. (2) Magnesium oxide three to twenty grains, or sodium bicarbonate five to twenty grains, or combinations of these, to control acidity. (3) Nitrate of silver one-quarter of a grain in one-half ounce of water might be substituted for the morning dose of bismuth and often hastened the healing of the ulcer. (4) Tincture of belladonna, one to three minims in liquid or tablet form, given three to six times daily before food with a view to diminishing the pylorospasm and supersecretion. (5) Anesthesin, three to five grains with bismuth might be substituted for the belladonna and increased the comfort of the patient. (6) Iron, preferably in some bland organic form, to combat the anemia. (7) Carlsbad Sprüdel salts, one ounce in warm water on waking was a laxative of merited reputation. (8) Liquid paraffin in doses of one-half to one ounce one-half hour before meals, three times daily. This seemed to decrease acidity and pylorospasm, diminish friction, relieve stasis and constipation, and bring about healing of the ulcer. It was usualy well tolerated.

Dr. MAX EINHORN said he wished to corroborate all the statements made by Dr. Hayes. In regard to the examination and application of the tube in gastric ulcer, they should be very carefully performed. He preferred the use of the stomach bucket because there was no

effort at all to bring it out. The tube, however, he had also applied in many cases. With regard to the thread test, he usually used the bucket, but he originally devised the use of the beads. His first endeavor was to make a study of the permeability of the pylorus. The great advantage in the use of the bucket was that material could be readily withdrawn from the duodenum. The combined method of thread and bucket might be employed. Dr. Einhorn presented a new instrument which would facilitate the introduction of the bucket. In most instances he introduced the bucket by having the patient swallow the bucket, but there were some instances in which this seemed difficult. Some patients said they could not swallow even a pill, let alone the bucket. Sometimes there was a spasm present. In some cases the water entered the stomach, but the bucket remained behind. He said he had had 124 cases in which he had used duodenal alimentation by means of a syringe, because in the ordinary method employed (fountain syringe) the length of time required for the food to reach the duodenum made it too cold.

Dr. Edward Wallace Lee believed that more attention should be paid to the study of stomach conditions, especially to the physical examination. Ulcerative tendency could then be recognized and even prevented. "Dyspepsia" was too often treated without looking for the cause; this seemed to be the "keynote" of Dr. Hayes' paper.

Dr. Bennet Sheldon Beach said there were four factors which should be considered: (1) The thread test was extremely useful and should play an important part in their findings. (2) It should precede the use of stomach tubes and other possibly traumatic methods. (3) The test for occult blood should also precede such examinations which were of a traumatic nature. (4) It was dangerous to aspirate by means of the bulb, and one should be very careful in withdrawing it because of the danger of causing erosions.

Dr. Hayes, closing the discussion, said he believed that nutrolone had a place in the treatment, especially where there was an over-acid condition.

**The Aim and Scope of the Psycopathic Clinic in Connection with the New York Public Schools.**—Dr. L. Pierce Clark read this paper. He said that for years the psychiatrist, neurologist, and educator had demanded more knowledge of the innate trends of manner, conduct, and temperament of normal and abnormal child life. For the psychiatrist such information was essential to assist him to mold the patient's life along lines that promised best mental anchorage; for the neurologist such facts would aid in preventing many of the neuroses and psychoneuroses; and for the educator a better information of the fundamental traits of intellect and character in children would enable him to gauge the lines of instruction to a more definite end. For these and many other reasons all demanded a thorough study of normal and abnormal child life. The school was the proper place for such studies and all public schools in the large cities should have a department for the clinical study of the frank nervous and mental disorders of children. The schools were the place for such clinics because they were in close touch with child life and the home. The parents had confidence in the public school system to deal with the mental development of their children. The school had also the training equipment, the personnel, and the financial support to adequately meet the issues concerned. When properly equipped and organized for the work, it could make clear the nature and degree of retardation and perversion of mental development of the child. The schools should call to its aid in this eminently co-operative work experienced physicians, sociologists, psychologists and educators to unravel this intricate problem of child study. The whole scheme called for the hearty support of all, as it was in line with the trend of the best thought of the day. They must study the beginning of mental disorders in order that the best means of preventing the nervous and psychotic disorders of adult life might be forthcoming. In accordance with the foregoing, Dr. Clark stated that last October a group of physicians had induced the Board of Education to form such a clinic under the direction of the Bureau of Ungraded Classes, since which date two experienced neurologists and psychiatrists and four social workers had been employed at analyzing the three thousand children in the two hundred special classes for the mentally defective, and more of such workers were being added as the organization progressed. One of the consulting staff was in charge of the central clinic at the Board of Education in its main office at Fifty-ninth Street every afternoon to examine in minutest details the more difficult or borderline cases. The Board soon hoped to have an observation school and a resident school for more prolonged and special training and treatment of the most stubborn cases. Careful case-records of the work were being kept and in time scientific and public information of the lessons drawn from the work would be given out. The idiot and imbecile group would be forwarded to State institutional care as rapidly as provision could be arranged for in such colonies. By so doing the clinic and school would give its greatest attention and study to the moron, the neurotic, and the delinquent child.

Dr. August Hoch said he was interested in the excellent program which had been presented for the care of these defective children. They were living in an impatient time, one that did not help in solving these problems. Along the lines outlined a great deal could be done in advising and guiding these patients. As a psychiatrist he had been interested in the study of the personality that came to patients after a breakdown or insanity. He was especially interested in learning what kind of people they were, and what traits they possessed which made them go in the wrong direction. Most of these individuals came too late for any sort of adjustment. There was an increasing appreciation of the importance of constitutional disorders in psychosis, as well as in neurosis. The speaker referred to the work of Dr. Healy of Chicago in the study of abnormal children; this work had shown how much could be done in finding out the genesis of the disorders. Such work was justified and by it a great deal more could be learned regarding these abnormalities. The Public School Institute work was interesting and had a place in the care of defective children, and Dr. Clark deserved great credit for the work he had done.

Dr. Foster Kennedy said that a few years ago the neurologist was directing his energies to solving the problems of structure which were mainly mechanical. A reversion had occurred from that point of view and now they were studying the individual from the psychical side. There was hope now that they might free themselves from such words as "hypnotic suggestion," "neurasthenia," etc. The study of the psychopathic child would enable them to differentiate the neurasthenic child and to separate these children into various types. By getting a knowledge of these different groups it might be possible to apply the remedy. The children who were defective in their motorium could possibly have one kind of education, and other types other kinds suited to their requirements. The neurologist and psychiatrist should be able to share in this work which would result in economic and social advancement.

Dr. Clark, in closing the discussion, said he agreed that there were types of temperament back of the precocious emotions in the infantile life in *ticeurs* and that the disturbance of the ambivalency of equality of emotional attachment to each parent was in greater part due to the inheritance of a certain type of temperament which, because of its strong determination to the hate polarity made one think that it was really atavistic in component. It would seem to be a predominant trait that many such individuals inherited, which was fortunately eliminated in most individuals. While the whole conception of the tics as laid down by him might be somewhat differently formulated in the future, he was confident the essential foundation of the concept would remain.

---

## NEW YORK ACADEMY OF MEDICINE.

### SECTION ON PEDIATRICS.

*Stated Meeting, Held January 9, 1914.*

Dr. Godfrey R. Pisek in the Chair.

**A Case of Hereditary Lues.**—Dr. Sara Welt-Kakels presented this case. The patient was an infant 6½ weeks of age. The parents were apparently perfectly healthy and denied having ever had any venereal infection. They had been married three years and this was the third child. The first child was still-born, and the second, according to the mother's statement, died of asphyxia at birth. This infant had been delivered normally and was apparently well until two weeks of age, when an eruption appeared and spread over the body. The eruption was crusty and bleeding about the mouth and nose, and breathing was difficult. The liver

and spleen were enlarged, and the urine contained a considerable amount of albumin. About 90 per cent. of these cases showed that effect in the beginning. The Wassermann reaction was strongly positive. As they all knew, there was no hereditary lues of the child without syphilis of the mother. Dr. Kakels said that it was her custom to treat such children with bichloride in small doses. This method of treatment had not been followed by diarrhea or blood in the stools. The dose was one milligram and not more than six or eight doses were given.

Dr. HENRY KOPLIK said that many of these children when treated with salvarsan or neosalvarsan died. It was difficult in the new-born to gauge the exact dose and many did not bear salvarsan well. In his hospital work he did not use it. He obtained excellent results with calomel and iron. He did not favor the hypodermic use of mercury.

Dr. THOMAS S. SOUTHWORTH assured Dr. Koplik that calomel was used to some extent in cases of this kind in this country. He had long used it in the Babies' Hospital and Dispensary, following Dr. Jacobi's method —one tenth of a grain three times a day. The way in which congenital syphilis cleared up under this treatment plus mild inunctions when babies were at the breast was remarkable. At the Babies' Hospital Dispensary they very rarely lost a baby from this cause when it was breast fed. The high mortality from hereditary lues as was often given had always been a source of wonder to him in view of the good results that they had obtained in treating these cases. In regard to the nasal treatment of hereditary lues he had found that a small amount of oleate of mercury in albolene dropped into the nose had a very beneficial effect on the mucous membrane.

Dr. L. E. LA FETRA said that in cases in which the eruption was intense and the child in very bad condition salvarsan was of the greatest service and would save some babies that otherwise would die. The salvarsan could be given in one or two injections at an interval of a week or ten days; then mercurial treatment should be used, both by inunctions and internally. It often happened that a patient returned with a relapse of the Wassermann reaction after having been treated with salvarsan alone and one had then to return to the mercury, so that it was advisable to employ the mersury from the first.

Dr. GODFREY R. PISEK said that in complicated serious conditions as syphilis complicated with pneumonia, salvarsan, because of its quick action, would be indicated, but mercury was to be preferred in ordinary cases.

Dr. SARA WELT-KAKELS, in closing the discussion, said that she did not administer the bichloride by way of the mouth, but used deep intramuscular injections. One should watch very carefully for blood in the feces and for albumin in the urine. Calcium (5 per cent.) with sugar was an excellent adjuvant in these cases.

**Hairpin and Stone in the Bladder.**—Dr. SARA WELT-KAKELS presented an *x*-ray plate showing a hairpin and stone in the bladder and related the history of the case. The patient was a child nine years of age, who had complained for two and one-half years. At the time that she first saw the patient she was complaining of severe pain in urination and burning sensations. The urine showed the presence of much pus. In making an examination per rectum the examining finger met with resistance, and the *x*-ray had revealed the nature of the trouble. The child was operated upon and made an excellent recovery.

**An Experiment in Collecting Human Milk for Hospital and Dispensary Use.**—Dr. RAYMOND HOOBLER read this brief paper in which he said that he had received the inspiration for this work from Dr. La Fetra's service at Bellevue. He had found that among the poor mothers who had more milk than was required for their own infants were willing to sell the surplus. The mothers who were willing to sell their milk were subjected to the Wassermann test and were instructed in matters of diet and hygiene and shown how to draw their milk. The milk was also subjected to examination. The cost of the milk by this plan was ten cents an ounce. This was a plan that was of benefit to the poor mothers who needed the financial aid and at the same time provided mother's milk for premature or delicate infants who could not survive without it.

**A Simple Method for Making Casein Milk.**—Dr. RAYMOND HOOBLER read this paper. He stated that the difficulty of making casein milk had stood in the way of its more general use. The process was so complicated that it was not practical in the home. Even if the casein was passed through a seive five times the curd still settled and even clogged the nipple, making it necessary for someone to assist the baby in getting its food. He had found that casein flour could be used in making the casein milk, and that the work of preparation was by this means very much simplified. The mixture was smooth and the curd did not settle in the bottle. They had used these casein flour mixtures at Bellevue during active service in August and September, 1913. The fat-free buttermilk was used with the casein flour. The casein flour cost forty cents a pound and one pound made forty-four quarts of casein milk; to make the same amount from casein curd would require twenty-two quarts of milk.

**An Experiment in Milk Stations.**—Dr. S. V. HAAS read this paper, in which he reminded them that he had stated in a discussion before the Section in March, 1911, that there were two serious errors in the milk stations as constituted. The term milk station was bad because it led the laity to consider milk as the important factor and cow's milk feeding as the method to be followed, thus subordinating by inuendo breast feeding and hygiene. Again the dispensing of milk was unnecessary either as a premium or as a method of furnishing good milk. It was also undesirable for the mother who was required to go to a distant station for her milk supply. The practice of dispensing milk was not desirable for the station since it increased the cost of maintenance. It also deprived the authorities of a method of inspection not otherwise possible. If the milk were purchased in open market and the child became ill, the source of supply could be investigated at once. In order to test these points rooms were set aside in Lebanon Hospital under the auspices of the Social Service Department and the Pediatric Department of the hospital. The training school supplied the nurses who received the social service experience as a part of their course, while the Pediatric Departmnt furnished the medical supervision. Since April, 1912, 455 babies had attended the milk station; of these 384, or 84.4 per cent., were breast fed; 13, or 2.8 per cent., were on mixed feeding; 58, or 12.7 per cent., were artificially fed; 14, or 3.0 per cent., died, two of which died of malnutrition. The average attendance was 19 infants and the average length of time under observation was 14 weeks. They felt justified in concluding that these stations should be called Baby Stations or some other name not containing the word "milk." Milk should not be dispensed at these stations for the reasons pointed out in the early part of the paper. A Baby Station could be successfully conducted without dispensing milk, and breast feeding would thereby be encouraged. The mortality statistics of a station conducted without the dispensing of milk compared favorably with those obtained by other methods.

**Two Years' Observation of Milk Station Infants.**—Dr. MARK S. REUBEN presented this paper. He stated that his study was based on about 1500 feeding cases observed at the Vanderbilt Clinic Milk Station and the Vanderbilt Clinic Pediatric Department since January 1, 1909. Nearly 500 of the cases had been observed for about one year. About 900 of the infants were artificially fed, about 500 were breast-fed, and about 300 received both breast-milk and artificial feeding. Only 19 infants had died from January 1, 1912, to June 1, 1913, and of these five had been to the milk station only once. Of the remaining 14 not one died of gastroenteritis. There were four factors which were conducive to a low mortality at the milk stations, education of the mother, clean milk, the nurse, and the physician. Of these the education of the mother was by far the most important element, though the others were important adjuvants. Anything that prevented the nurse from visiting the homes of the mothers regularly and frequently detracted from the efficiency of the milk station, as it was only by this means that the mothers could be taught to prepare the formulæ accurately and the other details of infant hygiene could be impressed upon her. The best advertisement to induce the mothers to bring their infants to the milk station was the knowledge that the milk station babies were doing well. They had found that the statement that breast feeding was falling into disrepute was not borne out by their experience. There were three reasons why so many of the infants brought to the milk stations were artificially fed: (1) Because of the large percentage of mothers who did outside work after marriage; (2) Because many mothers become gravid before their infants were three or four months old; (3) Because of

the indifference or ignorance of the attending physician who was responsible for the artificial feeding of many infants that could and should have been breast fed. The essayist believed that these mothers should be taught how to prevent conception, as frequently the exhausted condition of the mother induced by excessive child-bearing resulted in premature and atrophic infants. Such teaching would have a great influence in reducing infant mortality and would permit of breast feeding in many cases that were artificially fed. In cases of insufficient breast milk every expedient should be tried before resorting to supplementary feeding. Even when supplementary feeding was employed, every effort should be made to increase the supply of the mother's milk and as soon as this became sufficient the supplementary feeding should be discontinued. The only reliable method of determining the sufficiency of the breast milk was by observing the infant for at least one week when it was on the breast alone. It was paradoxical but true that the most difficult task the physician had was to persuade mothers not to institute artificial feeding when the milk supply was sufficient in early infancy, and to induce them to begin artificial feeding in later infancy when the breast milk was very scanty and the infants were practically starving. Very few women who visited the milk stations could nurse their infants longer than twenty-seven to thirty-two weeks. It had been their rule to wean the infants when their weight became stationary, or they lost weight for two successive weeks, all other causes having been excluded. Weaning in two weeks at this time was preferable to mixed feeding until the end of the first year. In later infancy when the milk supply became insufficient, it was also of inferior quality and the infants put on mixed feeding did not do as well as those weaned and fed artificially. The cases that in early infancy did not do well on breast milk were those in which the supply did not increase, and these cases did better if taken off the breast entirely. One should try supplementary feeding for at least a month before taking the child off the breast entirely. If, however, at the end of this time there was no increase in the milk supply one should not hesitate to take the child from the breast entirely. This was not a plea for artificial feeding, but one should not wait too long before beginning the artificial feeding. The highest weight curve at the end of one year was shown by those infants who were breast fed until the supply became insufficient, usually from twenty-seven to thirty-two weeks, and then weaned in two weeks and put entirely on artificial food. The second highest weight curve was shown by those infants artificially fed from birth, and the lowest weight curve at the end of one year was shown by those infants breast fed for the entire year, being due to mild starvation after the sixth month. The breast fed children weighed more than the artificially fed at the end of six months, but after that the artificially fed children gained much more rapidly. The keynote of successful artificial feeding at the milk stations depended on the degree of simplicity of the milk formula and how well the mother understood its preparation. Over 90 per cent. of the artificially fed infants did well on simple dilutions of whole milk to which carbohydrates were added to make up the requisite number of calories. In twelve hundred cases they had met only one case in which there was an idiosyncrasy to milk. Of 200 feeding cases that came to their attention at the milk station, only 19 per cent. had been put on milk formulæ, and 80 per cent. had been on patented foods. The explanation of this was ignorance as to how to prepare fresh milk. Infant feeding could be made both simple and successful in the majority of cases. They never used lime water, barley or oatmeal water, or top milk mixtures, unless there was an indication for their use. They were thoroughly convinced that in most cases they were useless and could be dispensed with. In feeding healthy infants they usually began with a one in three mixture; seldom was it necessary to prescribe one more dilute. The quantity given at each feeding was increased by one ounce every four weeks, and the strength of the mixture was increased as the weight and the symptoms indicated. On the whole they had found that infants could take much stronger mixtures than were usually given. They could usually take whole milk at six and one-half to seven months. No infant was given more than one quart of milk daily during the first year. When an infant stopped gaining on that quantity flour was substituted for part of the sugar and later cereals in the form of gruels were added. At nine months broths and zwieback were given, and vegetables finely mashed when indicated. A dextrine maltose preparation of sugar was given in every case unless there was some contraindication (one level teaspoonful to every ten ounces of mixture). This sugar was contraindicated in infants under two months of age, in those having a tendency to constipation, and when there was a tendency to vomit. It was distinctly indicated for babies that were much under weight. They had found that dextrin maltose caused the greatest gain in weight, cane sugar less, and lactose the least. The effects of these sugars on the digestive tract was also different. Lactose had the least and maltose the greatest tendency to produce vomiting. Lactose was also the most laxative and dextrin maltose the least so of the sugars. Even in the feeding of sick infants they had found that the simple dilutions gave excellent results, though every sick infant was a problem in itself. In cases in which there were gastrointestinal symptoms they never gave dextrin maltose until the symptoms had subsided. In these cases they used the flours more freely than in healthy infants. In order to meet indications they had used skimmed milk and *Eiweiss milch*. The essayist presented a study in calories which he summarized as follows: The caloric estimation of an infant's food was of distinct value in beginning to feed a healthy baby on the bottle, as it gave a definite method of ascertaining about how much food the infant needed; in feeding atrophic and puny babies, since they knew that these babies needed more calories than did normal infants; and in infants who were not thriving, since an estimation of the calories would sometimes reveal that the infant was getting a food too high or too low in calories. In studying the problem of why some infants did not thrive, they had been much impressed by the fact that the most common cause of this was the irregularity and infrequency of the visits made to the milk station; for an artificially fed infant to increase steadily in weight the food must be increased in quantity and in quality regularly about every ten to fourteen days. Other reasons for failure to gain properly were ignorance or stupidity on the part of the mother in the preparation of the formula, or some constitutional disease in the infant.

**The Infant's Milk Stations: Their Relation to the Pediatric Clinics and to the Private Physician.**—Dr. S. Josephine Baker read this paper. She stated that the Bureau of Child Hygiene of the Department of Health was organized in 1908 for the purpose of pursuing a progressive and constructive policy with relation to the health of the children of the city. While its activities included practically all features of child welfare work in relation to health, one of its functions was the attempt to reduce infant mortality. The death rate of children under one year of age from all causes was 144 per 1,000 births in 1907 and had shown but slight fluctuations from that figure during the previous four years. It was felt that former methods of dealing with this problem must be discarded and a campaign of educational prevention instituted, in order to make a definite imprint on this excessive mortality. As a result of this change from the purely corrective work of the past to the preventive method of instructing the mothers as to how the babies might be kept well the death rate for the year 1908 was reduced to 128 per 1,000 births. It was felt that a year-round campaign must be instituted if true preventive work was to be done. An appeal to the Board of Estimate resulted in an appropriation which allowed for the establishment of fifteen Infant's Milk Stations to be maintained under the control of the Bureau of Child Hygiene. The City of New York had ample facilities for caring for sick babies, but until the establishment of the milk stations practically no facilities for providing proper instruction in "how to keep babies well." In 1911 an Association of Infant's Milk Stations was formed embracing all the prominent agencies engaged in combating infant mortality. By this means the records could be kept uniform and the city districted so as to prevent overlapping of the work. The year 1911 showed a death rate of 112 as compared with 125 in 1910, or an actual numerical decrease of 1162 deaths. As a result of the proved efficiency of this work an increased appropriation was granted the Board of Health sufficient to establish forty additional milk stations, making fifty-five in all under the Bureau of Child Hygiene. The Infant's Milk Stations were not children's clinics; their purpose was rather to provide instruction in the proper hygiene and feeding of infants. One of their most important achievements was the en-

couragement of breast feeding. Each station was in immediate charge of a trained nurse who had an assistant, and a physician was in attendance each morning during the summer. The milk now sold in these stations was "Grade A. Pasteurized," for which the company charged eight cents a quart, a much lower rate than the regular market price. It was dispensed in one quart bottles only, and was subjected to constant analysis and inspection by the Department in order to see that the standard was maintained. In the absence of the physician, the nurse gave a simple formula appropriate to the age of the infant. (These formulæ were devised by a Committee of which the President of the Pediatric Section, Dr. William P. Northrup, was Chairman). The mother was instructed to return with the infant when the physician would be present and then the child was thoroughly examined and a suitable individual formula prescribed for each case. The physicians assigned to duty in these stations were competent, thoroughly trained men and women; only those were selected who had demonstrated their fitness in the specialized work of infant hygiene and feeding. Sick babies were not treated at these stations unless the illness was caused by an error in diet and was amenable to dietetic treatment. Even in such cases the treatment was not given unless the family was unable to employ a private physician and refused to go to a dispensary or hospital. With each baby referred to a physician, or a hospital, or dispensary, was sent a reference slip, giving the name and address of the child and the formula which had been used in feeding. Requests had been made that all dispensaries and hospitals send similar reference slips to the milk station after the baby had left the care of the institution. It was evident that such data were of immense importance, saving much valuable time that might be lost in attempting to find the best type of feeding for the child. When babies were once registered at the milk station, they were kept under continuous observation. If death occurred either under the care of a private physician, a pediatric clinic, or in a hospital, the death was charged to the record of the milk station. The milk stations welcomed the cooperation of the private physician, and many sent babies to the stations for instruction of the mothers as to how the formula was to be prepared. When a physician did this the doctor at the station did not see the baby. Under no circumstances was any employee of the Department of Health allowed to take as a private patient any person with whom he came into contact in an official capacity. During the year 1913 a total of 49,904 babies were cared for at these milk stations; of this number, 9,295 had been carried over from the previous year. The milk dispensed amounted to 2,367,495 quarts, and the nurses and their assistants made 262,121 visits to homes. During this period there were 145 deaths among the milk station babies, three tenths of one per cent. of the number enrolled. Of these deaths ninety-seven were due to diarrheal diseases and 48 to other causes. During the year 1912 the infant death rate was 105 per 1,000 births, and during 1913, this had been further reduced to 102. The reduction of infant mortality in New York City had been greater during the past 10 years than that achieved by any other large city in the country. With the exception of Rochester, the infant death rate in New York City was lower than in any first or second class city in the State. During 1913 there were 500 fewer deaths than during 1912. That the infant's milk stations had been the largest factor in this result there could be no doubt. The Department of Health, through the Bureau of Child Hygiene, believed that only by perfect cooperation and thorough understanding of its methods could the best results be attained. It was the earnest desire of the Department to cooperate to the fullest extent with private physicians, pediatric clinics and babies' hospitals; it was also its earnest desire that there should be similar cooperation on the part of the latter.

Dr. Henry Koplik said that he believed in the work of the milk stations and the *gouttes de lait* consultations, and at the same time he recognized the value of the prophylactic work done by the Board of Health. They did ideal work among the well babies. It did not do to place too much reliance on statistics; many births escaped registration and this altered the value of the mortality statistics. They would do well to consider the good work done rather than the statistics. Several of Dr. Reuben's statements he could not accept. For instance, Dr. Reuben had spoken of a baby of eight months which weighed thirty pounds and another of one year weighing twenty-seven pounds; these were abnormal children and had no place in the paper. Dr. Reuben said that if a baby did not thrive on breast milk it should be taken from the breast and fed entirely on artificial food. The breast should be utilized as far as possible. Though the infant received but two breast feedings daily they should not be given up in early infancy. Again, Dr. Reuben advised weaning babies at the age of eight months in two weeks' time. This was too short a time for a baby that was thriving. The weaning should be gradual, extending from the ninth to the eleventh month. One should never take a young infant from the breast while there was any milk. The best plan was to utilize all the breast milk you had and then add the bottle to supplement the deficiency.

Dr. Henry D. Chapin said there were two points in Dr. Reuben's paper to which he wished to call attention. Dr. Reuben had said that if after a fair trial there was no gain in weight it was useless to continue trying to use the breast. The State Department of Agriculture had made investigations regarding the milk supply of animals and had found that individual animals had their limit as to milk supply and that this could not be greatly altered by feeding and other measures directed towards securing an increase in the supply of milk. If in a mother who was in fairly good health and living under good hygienic and dietetic conditions the supply of milk was not increased, it was useless to expect much change. The second point to which the speaker called attention was that of simple formulæ. A few years ago the formulæ were so complicated that no one could remember them, but now they were in danger of going to the other extreme in using too simple formulæ. It was necessary that the food elements should be in the right proportion, and it was important to remember that the food elements were not interchangeable; for instance, carbohydrates could not be substituted for fats without destroying the proper proportion of the elements. It was to be feared that some of this simple feeding would result in a crop of rickets in the future.

Dr. Charles Herman said that frequently statistics were of little value, but those of the infant mortality as given by the Department of Health during the last few years could be considered accurate. Even if all births were not reported, the percentage reported was very high and had remained quite constant during these years. The important part was that the infant mortality rate had diminished regularly from year to year. In order to obtain a more definite idea of how much an infant welfare station could accomplish, the following experiment was made at the station of the Vanderbilt Clinic. Two square blocks in the immediate vicinity were chosen. The total infant mortality, the mortality from diarrheal disease, from congenital debility, and from respiratory diseases in this area for the years 1907, 1908 and 1909 was known. In 1911 the station was established. It was found that there were ninety-five babies in these two blocks but of these only 25 per cent. were registered at the station, although it was so near to the area selected for study. This emphasized the absolute necessity of having a visiting nurse. After the station had been in operation for three years the infant mortality rate in this area could be computed and a comparison of conditions before and after the establishment of the milk station made. In order to obtain the best results there should be a close association between the infant welfare station, the outpatient pediatric department, the babies' ward, and the maternity ward. The last in order to obtain breast milk. At the Lebanon Hospital they were very fortunate in having all four departments together.

Dr. Thomas S. Southworth said that he could not quite agree with what Dr. Chapin had said in regard to taking a baby from the breast if it did not thrive after a fair trial. What was a fair trial? Every bit of breast milk that the child could get was of advantage. Many of Dr. Reuben's observations were most true, but he implied that the breast should be stopped when the child ceased to gain with complementary or supplementary feeding. This was an open question. Dr. Reuben was dealing with dispensary cases and had admitted that the supplementary feeding led to overfeeding and that this was the cause of failure to get good results in his cases. Where children were given the supplementary feedings in an intelligent way one could get as good results with them as with entirely artificial feeding. Again, after the age of eight or nine months, one was not looking so much for a

slightly larger gain in weight as for good general development.

Dr. L. E. La Fétra said that the experiment carried on by Dr. Hoobler in his Bellevue wards had been very successful; since it was demonstrated that good breast milk could be obtained by such a plan. Breast milk was frequently absolutely necessary to save the lives of premature and feeble infants, and Dr. Hoobler was deserving of much credit for his solution of a difficult problem. The method which was described of making albumin milk with casein flour was easy compared with the older methods, and this was a distinct advantage. In regard to Dr. Reuben's study of infant feeding in dispensary babies, Dr. La Fétra said he believed that they were all agreed that mothers should be given every encouragement to nurse their babies entirely or in part, and that every ounce of breast milk should be conserved, except in those rare cases in which it acted as a poison. This principle should be adhered to not simply because of the greater digestibility of the breast milk, but because of the human protective principles that were carried over from the mother's blood.

Dr. William Shannon recalled that, two years ago in speaking before the Section, Dr. Jacobi had said that practically all mothers could nurse their infants. This was not so. Dr. Shannon asked Dr. Baker if the cool summer had been to any extent effective in modifying the infant mortality statistics.

Dr. J. Finley Bell of Englewood, N. J., said that in Englewood he had succeeded in interesting wealthy people in the effort to obtain mother's milk for the hospital and the plan had worked well. The milk had cost them only about half the amount it had cost Dr. Hoobler. Possibly the reports of the results attributed to the education of the mothers were overdrawn. Many of the mothers were very ignorant and accustomed to uncleanliness, while the making up of a milk formula was a rather technical procedure. This factor should be considered before refusing to give milk to such mothers. It did not seem necessary to jeopardize the lives of the infants in order to educate the mothers. One weak point was that though the milk was prepared for the baby the mother was allowed to care for the nipples. In their work they had cared for the nipples and delivered them wrapped in waxed paper. Dr. Bell thought that the formula on the card passed around would underfeed an infant of the age for which it was designated.

Dr. Godfrey R. Pisek said that the feeling of antagonism toward the Board of Health's work in this direction had almost gone by, and the profession realized that the Health Department was doing efficient work and physicians were ready and willing to cooperate with them.

Dr. Mark S. Reuben, in closing the discussion, said that the only reply he could make to Dr. Koplik was that there was no one who misunderstood like one who would not understand. There was no evidence to show that the children fed on the simple mixtures did not do as well in every respect as those fed on the complicated ones so popular a few years ago. The infants weaned at the eighth or ninth month and fed artificially as described were not backward in development. Dr. Reuben said that, while he did not believe in taking the child from the breast for any trivial reason, there were certain cases in which the mother seemed to be in fair health, an analysis of the milk showed that it had the food elements in the right proportion, and there was a sufficient quantity, yet the milk was toxic to the child. Such a child would not thrive while taking the mother's milk, but as soon as breast feeding was stopped the infant would do well.

Dr. Baker, in closing the discussion, said that Dr. Haas had spoken of the delivery of milk to the homes rather than dispensing it at the milk stations. There was no question but that the milk was a bait to the mothers. The city would be glad to be released from this responsibility, but without the milk the mothers would not come to the milk stations. Again, the milk companies would not deliver milk to the homes at the same reduced rate at which they furnished it to the milk stations. Dr. Baker said she had understood Dr. Haas to say that in his stations about 84 per cent. of the babies were breast fed. This, of course, would eliminate the need of dispensing milk and under such circumstances possibly home delivery might be effectual. Dr. Reuben should be endorsed in what he said regarding the simple dilutions of whole milk. They had been using these simple dilutions of whole milk in the milk stations of the Department with very satisfactory results. In regard to the criticism of the formula on the card passed around that it was deficient in calories, it was distinctly stated that this was only a temporary expedient, employed until the infant was given a thorough examination and the formula suited to his needs prescribed. These formulæ were gotten up about five years ago at the request of the speaker by a committee of which Dr. William P. Northrup was the Chairman. Of course they were all agreed that one could not depend entirely upon statistics. The statistics of Boston, Providence, and New York had been accepted by the Federal authorities as reliable, and these were the only cities whose statistics were thus accepted. Even if the birth registration were entirely disregarded, the actual numerical decrease in the number of deaths could be depended upon. If the same death rate had prevailed in 1912 that they had in 1907, there would have been about 6,000 more deaths during 1912 than actually occurred. The weather had been pretty much the same throughout the country during the past year, and while returns from other cities had not been fully received, from those that had come in earlier in the year, it appeared that New York had a more marked decrease in its infant death rate than any other large city in the country. There seemed to be but one reason for this and that was the active and systematic work that had been done by all the organizations interested in the reduction of infant mortality. One of the speakers had questioned the possibility of teaching some mothers the home modification of milk; their experience had shown that this was not only possible but eminently practical. There was a tendency to over-estimate the influence of milk in the problem of infant mortality. Probably 20 per cent. of the mortality could be laid to the milk, while 80 per cent. was due to lack of general care and education. It should not be forgotten that the excellent results of the work were due to the faithful service of those doing the work, from the Chief Inspector to the nurses and assistants. In closing, Dr. Baker invited the physicians to visit the milk stations to ask questions, and to offer criticisms.

Dr. S. V. Haas said that as an illustration of the value of the nurse to the milk station he wished to cite an instance at the Vanderbilt Clinic. When the Milk Committee dispensed the milk they had an efficient nurse in charge of the station, but later the Sheffield farms people dispensed the milk and had no trained nurse. During this time the attendance at the station fell away rapidly, but when a nurse was put on the service it again increased.

## WESTERN SURGICAL ASSOCIATION.

*Twenty-third Annual Meeting, Held at St. Louis. December 19 and 20, 1913.*

The President, Dr. Jabez N. Jackson of Kansas City, Mo., in the Chair.

(*Concluded from page 456.*)

**Ulcer of the Stomach in Children Before Puberty.**—Dr. Charles D. Lockwood of Pasadena, Cal., stated that ulcer of the stomach in children was relatively rare, but was probably much more frequent than heretofore believed. Many obscure abdominal conditions in children might be due to unrecognized ulcers. This paper was based on a case recognized and operated upon by Dr. Lockwood. A careful review of the literature had been made and a number of unreported cases had been discovered through personal correspondence with the members of the Western Surgical Association, other surgeons of large clinical experience, and Children's Hospitals of the United States and Canada. Etiology, pathology, and diagnosis of ulcer in children were discussed. The rarity of ulcer in children was explained by the position of the child's stomach, permitting rapid emptying, the small amount of hydrochloric acid present, and the good motility. The factors favoring ulcer were malnutrition, tuberculosis, burns, local injuries, leucemia, septicemia, anemia, and chlorosis in young girls and follicular gastritis. Ulcers in children were more often superficial erosions. The typical funnel shaped deep ulcer found in adults was rare; when present, it was not so often found in the pyloric region and perforation was common. Perforation had been reported most often through the posterior wall, through the lesser curvature near the cardia, and through the greater

curvature into the pancreas, as in his own case. Gastric ulcer should always be thought of in children with abdominal symptoms. Pain in the epigastrium, hematemesis and bloody stools were pathognomonic. The two latter were usually absent. Pain, worse at night, and indigestion were usually present. Diagnosis must be confirmed by microscopic examination of stomach contents and stools for concealed blood. Appendicitis was most often confused with ulcer. In Dr. Lockwood's case, palpation of the epigastric region during a paroxysm of pain first suggested ulcer. Gas could be felt to gurgle through the pylorus, followed by relaxation and relief of pain. This was believed to be an important diagnostic sign. Report of case. Girl, age 13. Suddenly seized with pain in left side. Later, pain worse at night, food vomited, rapid emaciation. Diagnosis of ulcer made through palpation, finding of blood in stomach contents and stools. Anterior gastroenterostomy was done with complete relief of all symptoms for three months, then recurrence of symptoms, second operation, followed by death from starvation in two weeks. Post mortem. Perforated gastric ulcer of greater curvature. Carcinomatous degeneration, with metastasis to liver, pancreas, kidneys, and glands. He then reported fifty-seven cases; of these fourteen were reported by correspondence and had not been previously published. The other forty-five cases had been reported in various medical journals, but never collected together. Of the total number of cases, only eleven had been treated surgically and these were reported in detail.

**Retrocecal Appendicitis.**—Dr. DAVID W. BASHAM of Wichita, Kan., stated that posterior drainage in these cases was far superior to the anterior with the Fowler position. The appendix should always be removed in these cases, if at all feasible, without compromising the safety of the patient. If the appendix was not removed, drainage was usually prolonged for many weeks, and even then the appendix might have to be removed in the presence of pus. The pressure and disturbance about the cecum frequently led to gangrenous perforation, followed by fecal fistula. If the drainage was unobstructed, these fistulæ generally healed spontaneously.

**Inoperable Cancer: The Best Methods of Discovering Its Activity. A Study of Heat in Cancer.**—Dr. J. F. PERCY of Galesburg, Ill., gave a brief résumé of the status of the treatment of carcinoma, and discussed specifically the literature bearing upon the relation of heat to cancer, and emphasized the vulnerability of cancer to heat. He referred to the work of E. Vidal as important, showing that the use of various serums, toxins, and vaccines produced no results in the treatment of cancer if they failed when administered to raise the temperature. He, therefore, concluded that these various methods owed their success largely to their fever-producing qualities. The various reports of diminution of malignant tumors, following infections such as erysipelas, assumed a new significance. He described his clinical and experimental researches in the application of heat in cancer. In experiments made on beef muscle, he showed that a mass 3 x 3 x 3½ inches was entirely coagulated in sixty minutes. Based upon experimental data given in his paper, the author stated that it was logical that there might be hope for the eradication of cancerous growths by attacking these morbid processes through their vulnerability to heat. It, therefore, remained to develop a method of applying heat to the tumor mass to a degree of efficiency that would permit of the greatest destruction of carcinoma cells with a maximum conservation of normal tissue cells. He mentioned the various methods possibly useful in this connection, and finally described his own. He spoke of it as a practical method for the application of heat in the treatment of carcinoma, and insisted that it had none of the objections that could, with reason, be claimed against the various other methods which he enumerated. The penetration of heat by the author's method could be definitely determined and regulated. Its applicability had almost no limitations where the malignant process was at all accessible. The required apparatus was not expensive, and was easily portable. The method consisted of the application of heat from an electro-cautery accurately controlled by a rheostat, and applied to the affected tissues, as outlined in the author's two previous papers. The point was made that heat, and not cauterization, was the object to be attained. Cauterization was responsible for the early formation of a charcoal core, and this interfered with the dissemination of heat, and later prevented drainage from the treated area. Without drainage, there was danger from the absorption of large quantities of killed cancer cells.

**Removal of the Appendix in All Cases of Appendicitis with Localized Abscess.**—Dr. VAN BUREN KNOTT of Sioux City, Iowa, stated that in speaking from an increased experience with the method, he advocated the removal of the appendix at the first operation in every case of appendicitis with localized abscess. He reported a series of 501 consecutive operations for appendicitis with localized abscess, in every one of which the appendix was removed at the first operation. In this series there occurred six deaths. One patient, a little girl, aged four years, died thirty-six hours after operation. Cause of death unknown, as it occurred at home in the country, some distance from the hospital. Man, aged 49, died sixteen days after operation from cardiac thrombosis. A boy, aged 17, died four days following operation from septicemia. Another patient, a woman, aged 31, died six days after operation from septicemia. A man, aged 27, died twelve days following an operation, from post-operative obstruction, further intervention being refused. The sixth patient, a man, aged 24, died from secondary hemorrhage the third day after operation. The ages of the patients included in this series ranged from ten months to 84 years. Attention was called to the fact that there was in this series no death from peritonitis. As it was the fear of inviting peritonitis by the free separation of adhesions during the removal of the appendix which seemed to deter many operators from an attempt at such removal at the primary operation, he claimed that the results secured in the series above quoted had removed practically the only objection to the removal of the appendix in abscess cases. He said that by this procedure the tendency to post-operative complications, including obstruction, subphrenic abscess, pylephlebitis, empyema, hepatic abscess, etc., was greatly lessened. During the separation of adhesions many small localized pus collections were often found which would have been otherwise overlooked. Thus was disclosed the reason for many a secondary operation, which was often, improperly, called a secondary abscess. In the author's hands the mortality of operations for appendicitis with localized abscess had by this method been reduced from eight per cent. to one and two-tenths per cent., and the claim was advanced that in the hands of men who were qualified to operate upon acute suppurative conditions within the abdomen, not only would mortality be lessened, but that convalescence was shortened and the tendency to postoperative sequelæ much diminished by the invariable employment of the method.

**Sarcoma of the Ovary.**—Dr. MILES F. PORTER of Ft. Wayne, Ind., based his paper upon a comprehensive study of the literature including twenty-six cases found reported in satisfactory detail, together with three cases of his own, making twenty-nine in all. Many sarcomas of the ovary had been overlooked in the past because of incomplete microscopic study, and for the same reason many tumors of the ovary were classed as sarcoma which in reality were not sarcoma at all. Averaging the percentages of sixteen observers, covering over three thousand cases of ovarian tumor, it was found that the percentage of sarcoma to all other tumors was 5.08 per cent. About 20 per cent. of ovarian tumors were malignant and about 5 per cent. were sarcomata; 50 per cent. of ovarian tumors ocurring in patients under five years of age were sarcoma. Contrary to the rule, sarcoma of the ovary frequently involved both organs. This double involvement occurred in about 20 per cent. of cases. Sarcoma was especially likely to occur in the two extremes of life. In his table the youngest patient was ten and the oldest sixty-two years of age. Doran reported a case in a seven-month fetus. The growth was usually rapid. Sarcomas of the ovary on palpation were in the majority of the cases solid or semi-solid to the feel. The ascites in connection with ovarian tumor indicated malignancy but not the character of malignancy, nor did the ascites mean that the disease involved the peritoneum. Sarcomatous tissue was often found in dermoids. About ten or twelve cases of carcinosarcoma of the ovary had been reported. Round-cell sarcomata were more common in the young, and spindle-cell more common in adults. Difficulty of classifying malignant tumors of the ovary was very great. The diagnosis was seldom made save at operation or post-mortem. A close study of each case in the light of their present knowledge would make it possible to make the diagnoses oftener in the future than in the past. Rapidity of growth of the tumor and rapid growth in a tumor that had been stationary for

a long time raised the suspicion of sarcoma. Pain was a prominent symptom in more than one-third of the cases. Disturbances of menstruation were more common in malignant than in non-malignant tumors. Especially was this true of amenorrhea. The mortality of the operation was much higher in children than in adults. The ultimate prognosis seemed the best in fibrosarcoma. A permanent cure could be expected in about 10 per cent. of all cases. Even in desperate cases, the results of the operation were sometimes surprising. Seeligman reported the successful treatment of a case with metastasis in spinal cord by arsacetin intravenously and *x*-rays. One case of cure lasting over a period of two years was reported as following operation and subsequent administration of Coley's fluid.

**Non-Papillary Benign Tumors of the Bladder.**—Dr. E. S. JUDD of Rochester, Minn., noted that out of 164 neoplasms of the bladder operated on in the Mayo Clinic, two were of the non-papillary benign type, springing from the muscular layer of the bladder. In a review of the literature he found thirty similar cases previously reported. In most of the reported cases, bleeding was the first and most marked symptom. Bleeding came apparently from the congested mucous membrane of the entire bladder but especially that covering the tumor. Those muscular tumors extended into the bladder and outward into the peritoneal cavity. The point of origin of the two herein reported was close to the meatus of the urethra. Both were pedunculated. Both were removed suprapubically. Both patients made uneventful recovery and had been well six and one and three-fourths years respectively. Pathologically, the tumors were covered by stratified mucous membrane similar to the mucosa of the bladder. Their appearance throughout was that of uterine myomas. They were composed of smooth muscle fibers and fibrous connective tissue.

**The Necessity of Conserving the Intercostal Nerves in Abdominal Incisions.**—Dr. E. P. QUAIN of Bismarck, N. D., had had occasion to operate on several patients who had previously been operated through lateral abdominal incisions placed in such a way as to sever intercostal nerves. The findings in such cases suggested a possibility that the omentum might have a greater tendency to adhere permanently to that part of the abdominal wall which had been deprived of intercostal nerve supply than to any other part of the parietal peritoneum. A series of experiments on dogs and rabbits was undertaken in an effort to determine whether these observations were correct. The following plan was adopted: Group I. The lower intercostal nerves were severed on one side through an incision near the costal margin without damaging the peritoneum. Group II. An incision was made in the linea alba, both sides of the parietal peritoneum were rubbed with gauze, care being exercised to apply an equal amount of trauma on each side. The wound was closed. Through a second incision at the costal margin on one side, segments of the intercostal nerves were removed. Group III. Same operations were made as in group II, with the addition of tr. iodi, gastric or intestinal contents in weak solutions to the peritoneum on each side. At autopsy there were no microscopic changes in Group I. In Group II, pathological changes were more marked on the enervated than on the normal side in seven of the eight experiments. Microscopic sections showed a more chronic infiltration and a delay in the reparative process in the enervated peritoneum when compared with corresponding sections from the normal side. In Group III, application of tr. iodi and of intestinal contents caused adhesions and chronic peritoneal infiltration to be more marked on the side deprived of intercostal nerve supply. Summary from fifteen experiments in Groups II and III: Adhesions were confined to the side of nerve extirpation in eight animals; two of the three cases with bilateral adhesions had most of the adhesions on the operated side; fibrin deposits were limited to the enervated side in one case; and one animal without adhesions had a more marked peritoneal infiltration on the operated side. There were three negative experiments. Hence, 80 per cent. of the experiments gave a positive answer to the question as to whether the destruction of intercostal nerve supply was of pathological significance to the peritoneum. That adhesions and chronic infiltrations were more likely to follow trauma and infection on an enervated than on a normal peritoneum were facts which argued strongly against lateral longitudinal incisions and in favor of transvere incisions.

**Conservative Operative Treatment of Long Standing Inversion of the Uterus.**—Dr. H. S. CROSSEN of St. Louis, Mo., stated that though inversion of the uterus had been skillfully treated by posture and taxis since the time of Hippocrates (400 B. C.) and by amputation in the more severe cases since the time of Soranus (100 A. D.), it was only within the last half century that conservative operative measures had been developed. At the present time hysterectomy was the treatment commonly employed in the long standing cases. In some of these cases, particularly in women past the age of thirty-five, hysterectomy was the best treatment. In other patients, however, especially in younger women, sacrifice of the uterus was not the best treatment. In such patients preservation of a functionating uterus was very important and might be obtained through a conservative operation. He mentioned the operative methods by which the long-time inverted uterus might be replaced and its functions preserved. Complete division of the anterior uterine wall and cervix (Spinelli, 1900) was the most satisfactory method. He reported a case operated on by this method and detailed the technique. The patient was 23 years of age and had a complete inversion of the uterus of a year's duration. In the trimming of the thickened uterine wall so that it could be enclosed within the shrunken uterine peritoneum, about one-fourth of the wall was sacrificed. The patient made a perfect recovery. Menstruation began the second month after the operation and had been regular and normal for eight months. The advantages of the Spinelli method were as follows: (A) Being vaginal, it minimized the amount of peritoneal contamination; a most important consideration when dealing with an infected structure. (B) As the reposition was accomplished by incision, there was not the bruising and perforation of the friable uterine wall, which had so often accompanied attempted reposition by dilatation of the constriction ring. (C) Division of the interior uterine wall was preferable to division of the posterior wall, because the work was thus more easily and accurately accomplished. The anterior uterine wall and anterior fornix laid toward the operator, hence were less deeply situated and more easily reached. Again, when the operation was anterior, the bladder might be lifted away, giving a wide space for investigation of the inversion-funnel and of the various pelvic structures, and also more room for the operative manipulations of incision, reposition, and suturing. Again, if there was a marked backward tendency, effective forward fastening of the uterus might be carried out through the anterior incision. Again, a suture line on the posterior surface of the uterine wall was more likely to form troublesome adhesions—to the intestines, leading to obstruction, or to the posterior pelvic wall, leading to adherent retrodisplacement. The points in favor of the posterior incision were, that it eliminated the extra opening for drainage and that the sacro-uterine ligaments might be conveniently shortened. But these minor advantages of the posterior incision were outweighed by the more important advantages of the anterior incision.

**Studies on the Function of the Periosteum.**—Dr. J. E. MOORE and Dr. J. F. CORBETT of Minneapolis had made a study of bone growth both in man and through experiments on animals. The conclusions from these studies were: Bones from which a portion of the shaft had been removed, healed in the presence of irritation by subperiosteal bridge of bone. Cutting the nutrient artery prevented the formation of subperiosteal bridge. As the nutrient artery supplied medullary bone and as the periosteum was left intact when the artery was cut, one might assume that the medullary bone was responsible for the subperiosteal bridge. Subperiosteal bridge might fill in gaps left in the periosteum; therefore bone cells were not absolutely dependent upon that structure even as a place of refuge. Subperiosteal bridge was more marked where it received obsteoblasts from two sources than from one. Fascia was a substitute for periosteum. In heterotopic transplants, no subperiosteal bone could be produced by irritation. This was somewhat surprising in that the heterotopic experiments were conducted upon rabbits. They knew that old scars in these animals frequently contained true bone, and that the periosteal device of Scheppelmann begot true bone in the peritoneal cavity. At the present day the periosteum was disregarded. The present day surgeon might be comparatively indifferent to the periosteum when operating upon bone. If it was convenient he preserved it, because the conservation of tissues was always good surgery; but if it was not convenient, he did not hesitate to sacrifice it, knowing that it was not an essential element in the healing of bone.

**Pseudo-Pancreatic Cysts with a Report of Four Cases.**—Dr. Frederick A. Besley of Chicago first suggested that the name should be changed, the present term not being descriptive of the pathological condition. In a review of the literature he found that Jordan Lloyd first accurately described the condition. An analysis of early case reports of so-called pancreatic cysts due to trauma seemed to show that most of them were probably pseudo cysts. A brief review of the anatomy of lesser peritoneal cavity was given. Four cases were reported. Two cases occurred in the service of the writer at Cook County Hospital, one at Wesley Hospital, and one at the Post Graduate Hospital. All four cases received a violent injury in the upper abdomen. Each case showed some immediate reaction from a mild peritoneal insult. A tumor developed in from ten days to three weeks and appeared as a mass to the left and above the umbilicus. In three cases the distended stomach was above the tumor and the colon below it. In the first case the mass projected above the stomach. Fat necrosis was observed in two cases and in two cases a fluid contained pancreatic ferments. The four cases reported were all treated by incision and drainage, and all of them made an uneventful recovery.

**Surgery of Puerperal Eclampsia; Suprapubic Cesarean Section.**—Dr. B. M. Ricketts of Cincinnati, O., read a paper on this subject in which he drew the following conclusions: (1) Medical treatment alone was of but minor importance. (2) Ambulancing eclamptic patients should not be done except in rare instances. (3) The cause of eclampsia had not been discovered. (4) The mortality of both mother and child was proportionate to the early hour of operation. (5) Celiohysterectomy was the method of choice in cases of infection, uterine rupture, or neoplasms. (6) Celiohysterotomy was indicated after the sixth month of gestation when eclampsia was manifested with or without convulsions in the absence of known infection.

## Books Received.

*The* Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

The Student's Handbook of Gynecology. By George Ernest Herman, M.B., F.R.C.P. (London), F.R.C.S. (England). Second Edition, Revised. Illustrated; cloth; 587 pages; price $2.50 net. William Wood & Company, New York.

A Manual of Medical Treatment or Clinical Therapeutics. By I. Burney Yeo, M.D., F.R.C.P. Fifth Edition. By Raymond Crawford, M.A., M.D., F.R.C.P., and E. Farquhar Buzzard, M.A., M.D., F.R.C.P. In Two Volumes. Cloth; 834 pages; price $6.00 net. William Wood & Company, New York.

Tropical Medicine and Hygiene. By C. W. Daniels, M.B., F.R.C.P. In Three Parts, with colored and other illustrations. Part I—Diseases Due to Protozoa. Second Edition. Cloth; illustrated; 277 pages; price $3.00 net. William Wood & Company, New York.

Tuberculin in Diagnosis and Treatment. By Dr. Bandelier and Dr. Roepke. Second English Edition. Translated from the Seventh Revised and Enlarged German Edition. By Wilfred B. Christopherson. Cloth; illustrated; 307 pages; price $4.50 net. William Wood & Company, New York.

A Course of Lectures on Medicine to Nurses. By Herbert E. Cuff, M.D., F.R.C.S. Sixth Edition. Cloth; 281 pages; price $1.25 net. P. Blakiston's Son & Company, Philadelphia.

Diseases of the Digestive Canal. By Dr. Paul Cohnheim. From the Second German Edition. Edited and Translated by Dudley Fulton, M.D. Illustrated; third edition; 389 pages; price $4.00. J. B. Lippincott Company, Philadelphia and London.

Leitfaden der Säuglingskrankheiten. By Dr. Walter Birk. Illustrated; paper; 256 pages; price 4.80 Mks. A. Marcus & E. Webers, Bonn, 1914.

Pathogenic Microorganisms. A Textbook of Microbiology for Physicians and Students of Medicine. By Ward J. MacNeal, Ph.D., M.D. Cloth; illustrated; 462 pages; price $2.25 net. P. Blakiston's Son & Company, Philadelphia.

## Therapeutic Hints.

**Treatment of Premature Baldness.**—G. T. Jackson and C. W. McMurtry state that by proper care of the hair and scalp much may be done to prevent the fall of hair. The maintenance of the fullest vigor of the body is an important means of preserving the hair. In alopecia præmatura idiopathica in which there is no local disease of the scalp one must rely upon stimulation of the circulation in the hope of bringing a richer supply of blood to the hair papillæ. Massage of the scalp should be done frequently and thoroughly. If done by an attendant the massage should be performed for twenty to thirty minutes three or more times a week. The masseur should use an emollient such as "sulphur cream":

℞ White wax, 6 drams.
Petroleum oil, 5 ounces.
Rose water, 2½ ounces.
Sodium borate, 36 grains.
Precipitated sulphur, 7 drams.

Deep brushing with a long bristled brush for a few minutes night and morning is an easy and effectual means of bringing an increased flow of blood to the scalp. Wire brushes are of doubtful value. Electricity and vibratory massage have their advocates. The only medicinal agent that seems to exert a specific action is pilocarpine. A favorite formula is;

℞ Pilocarpine muriate, 20 grains.
Cologne water, 4 ounces.
Rose water,
Absolute alcohol, āā ad 8 ounces.

This is to be well rubbed in night and morning.

Cottle speaks highly of the following lotion:

℞ Acetic acid, 4 drams.
Powdered borax, 1 dram.
Glycerin, 3 drams.
Alcohol, 4 drams.
Rose water, ad 8 ounces.

Tar in some form is said to promote the growth of the hair. One of Sabouraud's formulæ is:

℞ Oil of cade,
Lanolin,
Vaseline, āā 2½ drams.
Yellow oxide of mercury, 15 grains.

In alopecia pityrodes in which there is always some scaling of the scalp, which in its minor form is recognized as dandruff, and which may be so abundant as to produce thick, greasy scales, one should first seek to cure the seborrheal condition. If there is abundant scaling of the scalp olive oil or sweet almond oil with 2 per cent. of salicylic acid should be well rubbed into the scalp at night and an oiled silk or rubber cap put on. On the following morning the scalp should be washed with soap and water.

This should be repeated for several nights until the scalp is clean. The authors prefer cleansing of the scalp with the use of sulphur cream. R. Sabouraud recommends the following:

℞ Alcohol, 90 per cent., 8 drams.
Spirit of lavender,
Spirit of ether, āā, 6½ drams.
Pilocarpine muriate, 4 grains.
Water, sufficient to dissolve the above.
Ammonia water, 1 dram.

The four drugs that are of most use in alopecia pityrodes are sulphur, resorcin, tar, and mercury, and the greatest of these is sulphur.—"Diseases of the Hair."

### A NEW METHOD FOR ESTIMATING THE FUNCTIONAL CAPACITY OF THE KIDNEYS BY FORCED ELIMINATION OF PREFORMED UREA.

By G. W. McCASKEY, A.M., M.D.,

FORT WAYNE, IND.

PROFESSOR OF MEDICINE, INDIANA UNIVERSITY SCHOOL OF MEDICINE.

The measurement of the functional capacity of the kidneys, as an aid to diagnosis, has attracted extraordinary attention during the last few years. It would be difficult to overestimate the value of such methods in a large group of cases in which the outspoken symptoms of renal disease are masked or complicated by other symptoms due either to morbid changes in other organs, or more generalized disturbances of health dependent, for instance, upon perversions of metabolism. It is fully recognized that the mere presence of casts and albumin in the urine tells us little as to the extent of the disease which their presence indicates. It is true that their significance may often be correctly determined by correlative signs and symptoms, but sometimes this is difficult or impossible. In such cases, and in that other group in which more or less extensive destruction of renal tissue exists without albuminuria or casts, at least at the time of observation, the need of such aid as a functional test may furnish is pressing.

There are certain difficulties standing in the way of the practical application of a functional test which should be fully recognized. Chief among these is the very large margin, so to speak, of kidney function with which the animal organism is endowed. The surgeon removes one kidney, *e.g.* and if the other is of normal size and function the individual goes on his way none the worse, so far as can be seen, for the loss of one-half of his kidney structure. Not only so, but at least one-half of the remaining kidney can be removed without seriously curtailing his renal function, at least so far as the ordinary demands are concerned. If, however, an emergency arises involving extraordinary demands, or if some untoward circumstance, such, for instance, as a severe passive congestion, or the depressing action of some toxin, should temporarily inhibit renal function, the patient might easily succumb because of the limitation in quantity, and, therefore, in functional capacity of renal tissue.

Now this general biological law, while of the utmost importance for the conservation of the individual, makes it impossible to recognize the incipient stages of destructive lesions by a simple measurement of functional capacity.

Not only is there an extremely wide margin of surplus function, a considerable part of which may be sacrificed without serious detriment to the patient under ordinary conditions, but the size and functional capacity of the kidneys vary in different individuals. Sharply defined lines, cases on one side of which are normal, and on the other pathological, can not be drawn at all.

To still further complicate this problem extrarenal causes, especially in the cardiovascular apparatus, may greatly impair function without any structural alteration whatever, or at most only that of a slight and evanescent character. The coexistence of cardiac disease always suggests the operation of extrarenal causes. Other signs of cardiac weakness will usually be found if this is an important factor in the case. In any event the influence of extrarenal circulatory disturbances in producing passive renal congestion, and thus impairing renal function is a practical problem which the clinician must solve as best he can. This is, of course, often very difficult. It has an obviously important bearing on both prognosis and treatment, but even if it can sometimes receive only a probable solution, information regarding renal functional capacity is still of the highest value.

The object of this communication is to offer a clinical method of estimating one of the most important phases of kidney function in a manner more strictly physiological than the elimination of foreign substances, the information derived from which must be entirely inferential. I say "phase of kidney function" because it has been clearly demonstrated, experimentally and clinically, that renal function is extremely complex, and that "functional capacity" may be unimpaired, or at most slightly impaired in regard to the elimination of certain substances, and most seriously compromised in regard to others. This fact is too well known to require comment or verification. While there are probably other substances or groups of substances, the elimination of which by the kidneys may be differently modified by kidney disease, I will mention three because of their great clinical importance, as well as their fundamental relation to the entire question, *viz.*, urea, chlorides, and water. The first two of these, and possibly the third, represent clinically, and probably pathologically, certain fairly definite types of renal disease. It is perfectly obvious that the dietetic treatment of Bright's disease, which is paramount to all others, should, if possible, be absolutely controlled by the precise type of "renal block" present. To subject a patient to relative proteid starvation, when the renal impermeability is for chlorides only, or vice versa, is no longer justifiable. The clinical differentiation can be made, and should be made as directly as possible. It is not desirable to draw inferences when direct evidence is obtainable.

The phenolsulphonephthalein test, undoubtedly the most valuable test by elimination of a foreign substance introduced up to the present time, although

giving information of great value, does not make this differentiation. The statement of Rowntree and Geraghty, that its elimination corresponds with that of urea, certainly has many exceptions. In another paper[1] I have cited a number of my own cases in which the discrepancy was very marked. This question will be taken up later in this paper.

It was with the view of getting direct evidence as to the capacity of the kidneys to excrete urea that I took up the clinical study of its elimination after the ingestion of preformed urea by mouth. The study of urea excretion after the ingestion of variable quantities of proteid food was obviously unsuited, because of the relatively slow digestion, absorption, and metabolic change of such alimentary substances. Preformed urea, being readily soluble, and entirely non-toxic, could easily be taken into the circulation from the digestive tract in quantities, the prompt elimination of which would either be beyond the capacity of the kidneys, or at least beyond any possible physiological requirement. In this way it seemed to me, a very reliable estimation could be made of the capacity of the kidneys to excrete what is apparently the most important end-product of nitrogenous catabolism.

Not only is urea important as a constituent of the waste products normally removed by the kidneys, but by reason of its large nitrogen content, it seems probable that the renal mechanism for its removal is somewhat closely related to that concerned in the removal of the toxins responsible for the syndrome of Bright's disease, because unless these unidentified toxic substances differ from the entire group of ptomaines, leucomaines, etc., which have been identified, they also are nitrogenous in composition. The inference seems fair, therefore, that the capacity of the kidneys to eliminate urea, would bear a close relationship to their capacity to remove these toxic substances from the blood. At least it should furnish more reliable information than the elimination of any foreign substance.

The only reference that I was able to find in easily accessible literature was in Albarran,[2] who reports giving 20 grams of urea and 5 centigrams of methylene-blue daily for several days and finding that the curves of excretion corresponded closely. My purpose was to determine the maximum capacity of the kidneys for urea excretion in a given period of time, believing that this would be the most reliable criterion of their ability to depurate the blood of the nitrogenous toxic substances.

After studying the question theoretically and experimentally, the following technique was adopted:

*Method.*—About 6 A.M. the bladder is emptied. Two hours later the urine is collected, and at the same time the patient is given 30 grams of urea, dissolved in four or five ounces of water. Just before taking the urea, the patient drinks one-half of about six ounces of thin cereal gruel, taking the other half immediately after the urea. No other breakfast. The urine is then collected every two hours for 12 to 24 hours, the urea determined for each two-hour period, including the two hours preceding the ingestion of the urea, and from these data the curve of excretion is constructed.

It is not necessary to secure an exact nitrogen balance. With any ordinary diet, the urea output from 6 to 8 A.M., fourteen to sixteen hours after the last food taken, is too small to confuse the findings in any way. Unless the quantity of proteid food ingested during the preceding day is excessive, the exogenous urea will have been all or nearly all excreted by that time. A fairly low, *e.g.*, 50 gram, proteid intake for the day preceding, and the day of the test, meets every requirement.

There are several reasons why the urea is given in the manner, at the time, and in the quantity indicated. The morning hour is selected because the urea output will be at its lowest volume, and the observations, if limited to 12 hours, may be completed during the waking hours. A small quantity of liquid nourishment is chosen in order that the urea may be hurried through the stomach, from which absorption does not take place at all, into the intestines where absorption is rapid. A part of the gruel is given first because we found that the empty stomach frequently does not tolerate the urea solution well, and the remainder of the gruel is given afterward to remove the rather unpleasant flavor of the urea. Beer and coffee have both been used to mask the bitter taste, which resembles that of epsom salts.

After experimenting with different quantities of urea, varying from 20 to 40 grams, 30 grams was decided upon as about the proper amount, being amply large to test the capacity of the kidneys to their limit, or at least far beyond any possible physiological demand for functional capacity.

As a basis of comparison, the bi-hourly output of urea was studied under different dietetic conditions in cases with presumably normal kidneys. This is shown in charts Nos. 1 to 4, forming

GROUP I.—Bi-hourly output of urea on ordinary diets without administration of urea.

*Explanation.*—In all of the charts which follow the vertical lines indicate bi-hourly periods, the figures at the base of these lines showing the exact time, always commencing in the morning. The horizontal lines represent grams of urea, graphical-

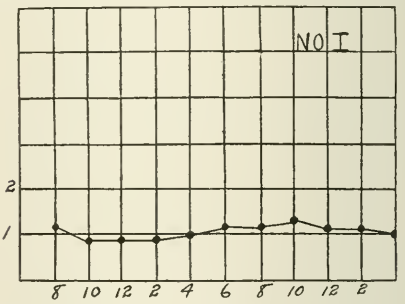

CHART 1.—Urea excretion in case No. 337—Tic Doloreaux—normal kidneys, on a diet of 50 grams proteid daily in three meals. Phthalein 2 hrs.—48 per cent. Urea excreted 12 hrs.—5.8 grams.

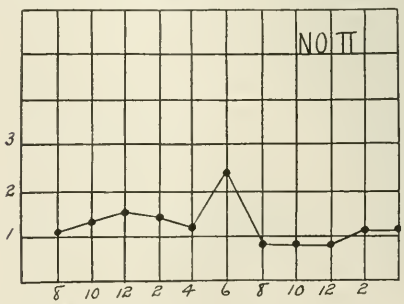

CHART 2.—Same patient as Chart 1, with 100 grams proteid daily. Urea excretion in 12 hrs.—9 grams.

ly shown, and also indicated by figures at the beginning of each line. The dot occurring on the vertical lines, as a part of the graphic line, always represents the urea output for the preceding two hours. When

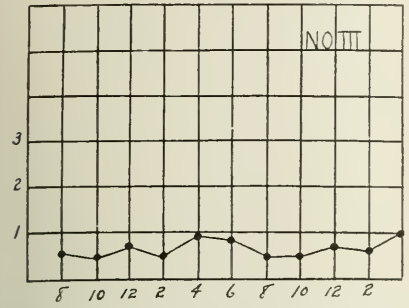

CHART 3.—Case No. 402—anemia with slightly damaged kidneys, still capable of doing good work. On 50 grams proteid daily. Phthalein—30 per cent. 12-hour excretion of urea—4 grams.

this occurs on the same vertical line with the x it represents the urea output for the two hours preceding the ingestion of the urea.

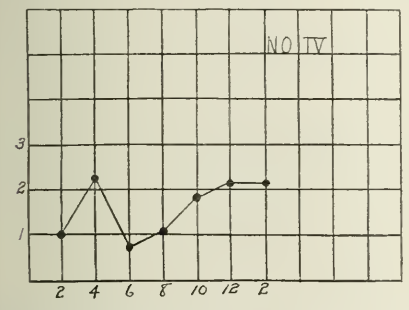

CHART 4.—Case of chronic gastritis—normal kidneys—on 65 grams proteid daily. Phthalein—record lost. 12 hour excretion of urea—10.3 grams.

Charts 1 and 2 represent the urea output in a man 25 years of age, with a remarkably large capacity for urea excretion as shown later in chart No. 5 from the same patient. There is a a notable similarity between the curves on a diet containing 50 grams of proteid and one of 100, the only difference being that the latter runs a trifle higher. In these two charts, both from the same patient, and in No. 3, from a patient with slightly damaged kidneys, on a 50 gram proteid diet, pretty evenly divided between the three meals of the day, there is a noticeable absence of any sharp rise or fall of urea excretion in connection with the digestion of meals. The urea from the food proteids can only be formed as fast as digestion, absorption, and the chemical processes of metabolism can be completed; and in these observations, excretion of the exogenous urea of one meal apparently merges into that from the next. In chart No. 4 somewhat wider fluctuations are observed with 65 grams of proteid daily, and with a single very large proteid meal they would undoubtedly be still larger.

The results of the ingestion and rapid absorption of 30 grams of urea are naturally much more striking. It is a crystalloid substance in solution, and unless retarded by gastric stasis usually enters the circulation through the intestinal wall very rapidly, and without any chemical change whatsoever, so far as known, is ready for excretion by the kidneys with a rapidity directly proportional to their functional capacity. It is perfectly well understood that this functional capacity is dependent upon several factors other than the structural integrity of the kidneys, such, *e.g.*, as the local neurovascular mechanism controlling the circulation of the kidneys, and, of course, the general cardiovascular conditions. Ordinarily the greater part of this urea will be in the blood by the end of the first two-hour period. During the second two-hour period, therefore, we should expect the maximal urea output. This is in fact what takes place in health. Just what the maximal output should be in any two-hour period following the ingestion of 30 grams of urea in normal individuals must vary considerably with the size of the kidneys, the activity of the renal circulation and of the renal epithelial cells which may very probably be influenced by toxic or nervous conditions and other factors known or unknown.

In charts 5 to 7 inclusive are shown what I believe to be the ordinary range of health.

GROUP II.—Excretion of urea in normal individuals in bi-hourly periods, following ingestion of 30 grams of urea.

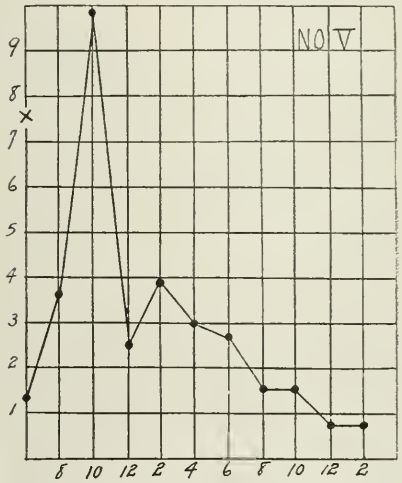

CHART 5.—Case No. 337—same as in Chart 1—normal kidneys. 30 grams urea given at 6 A. M. Phthalein—48 per cent. Highest output 9.6 grams—second bihourly period. Urea excretion 12 hrs.—25.5 grams.

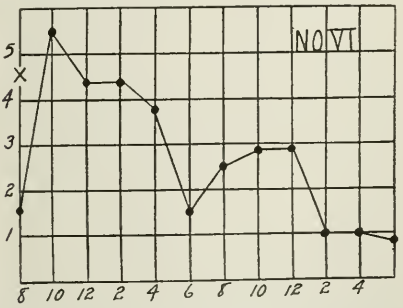

CHART 6.—Case No. 391—normal kidneys—30 grains urea given at 8 A. M. Phthalein—54 per cent. Highest output 5.5 grams—first bihourly period. Urea excretion 12 hrs.—22.1 grams.

*Explanation.*—Same as group I with the addition of an "x" in a broken vertical line which indicates the hour at which the 30 grams of urea were given.

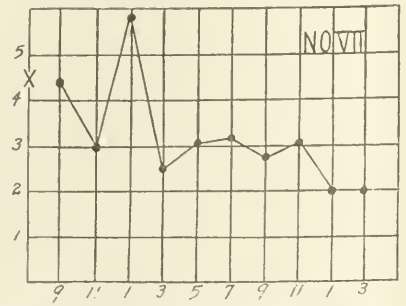

CHART 7.—Case No. 511—arteriosclerosis—kidneys with normal urea excretion—30 grams urea given at 7 A.M. Phthalein—25 per cent. Highest output 5.8 grams—third bihourly period. Urea excretion 12 hrs.—21.75 grams.

The following charts (8 to 14 inclusive) are selected from various cases, mostly pathological, the legends beneath each chart giving some information in regard to each case.

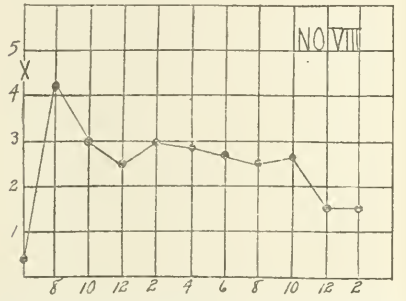

CHART 8.—Case No. 148—renal function for chlorides subnormal—urea excretion somewhat impaired—30 grams urea given at 6 A.M. Phthalein—32 per cent. Highest output 4.25 grams—first bihourly period. Urea excretion 12 hrs.—18.3 grams.

GROUP III.—*Explanation.*—Same as in group II. For diagnostic purposes these charts may be studied from several aspects, in addition to the maximum bi-hourly output already referred to. It

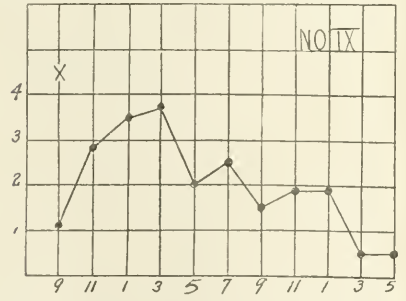

CHART 9.—Case No. 378—epilepsy—kidneys—30 grams urea given at 9 A.M. Phthalein—42 per cent. Highest output 3.7 grams—third bihourly period. Urea excretion 12 hrs.—16 grams.

seems worth while, in passing, to consider for a moment what would be the 24-hour output of urea if the highest bi-hourly rate were maintained for that time. In chart No. 1 on a 50-gram proteid diet, the 24-hour urea excretion on this basis would be about 15 grams. In Chart No. 2 on a 100-gram

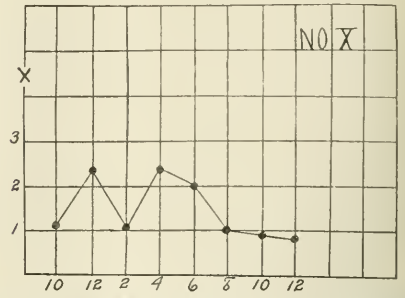

CHART 10.—Case No. 719—advanced endocarditis and myocarditis with chronic passive congestion of kidneys—30 grams urea given at 8 A.M. Phthalein—6 per cent. Highest output 2.4 grams—second and fourth bihourly period. Urea excretion 12 hrs.—10.25 grams.

proteid intake, it would be nearly 30 grams. In chart No. 5 from a normal individual after the ingestion of 30 grams of urea it would be about 120 grams, while in charts No. 6 and 7 it would be a

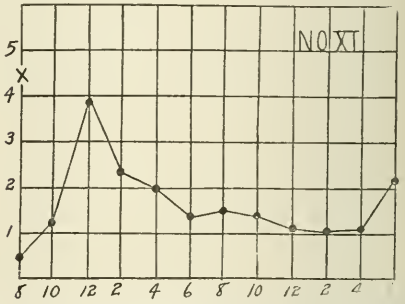

CHART 11.—Case No. 631—marked secondary anemia, cord degeneration and limited renal capacity—30 grams urea given at 8 A.M. Phthalein—21 per cent. Highest output 3.9 grams—second bihourly output. Urea excretion 12 hrs.—12.37 grams.

little more than 60. It would not, of course, be possible for the highest rates of excretion shown in charts 5 to 7 to be maintained for a very long time. The kidneys would soon become exhausted,

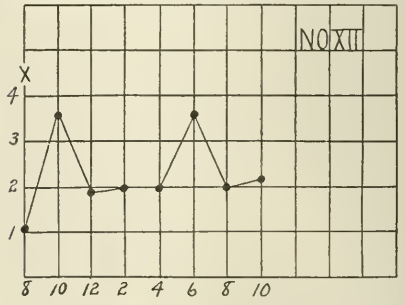

CHART 12.—Case No. 603—endocarditis, myocarditis, moderate renal impermeability to urea—30 grams urea given at 8 A.M. Phthalein—50 per cent. Highest output 3.6 grams—first and fifth bihourly period. Urea excretion 12 hrs.—17.67 grams.

even if it were possible to keep the blood charged with the high percentage of urea which we know

would be necessary, and which, according to Ambard's investigations, bear a certain definite proportion to the urea output in the urine at any given moment. Twelve times the highest bi-hourly output, however, gives us a factor which can be compared with the ordinary daily excretion on a full proteid diet, indicating the enormous reserve functional capacity of the kidneys. This is not suggested, however, as a diagnostic criterion.

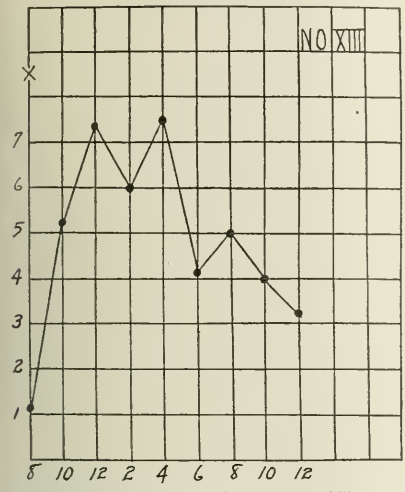

CHART 13.—Case No. 686—diabetes—permeability to urea normal—30 grams urea given at 8 A.M. Phthalein— 25 per cent. Highest output 7.5 grams—fourth bihourly period. Urea excretion 12 hrs.—35.35 grams.

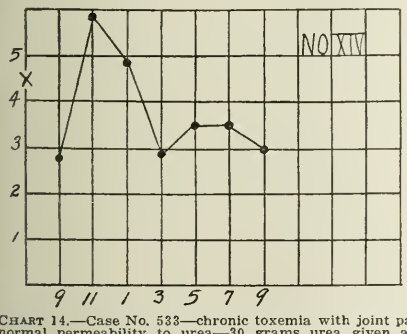

CHART 14.—Case No. 533—chronic toxemia with joint pains —normal permeability to urea—30 grams urea given at 7 A.M. Phthalein—45 per cent. Highest output 5.7 grams—second bihourly period. Urea excretion 12 hrs.—23.16 grams.

A more important consideration is that of the actual excretion during a longer period following the ingestion of the urea. For this purpose 12 instead of 24 hours has been chosen because of the practical difficulty of keeping up an accurate bihourly collection of urine during the night, and especially because the most important clinical data can usually be obtained within that time.

The entire curve for 12 or 24 hours often presents interesting fluctuations, the significance of which at present is not always clear. This gives us then for the clinical study of forced elimination of preformed urea:

1. The highest bi-hourly output, which seems to vary in health from 5 to 10 grams.
2. The total output in 12 hours.
3. The general character of the excretion curve.

The period during which the highest excretion occurs is of interest. It should be either the first or second two-hour period. If later, it may be due either to delayed absorption, or to a slow response on the part of the kidneys. The late, very wide fluctuations in the urea output found in some cases, after taking 30 grams, furnish pretty strong proof that the kidneys may for some reason fail to respond promptly to a large urea content of the blood, which certainly cannot rise and fall as the urea excretion sometimes does.

What are the standards of normal function calculated on this basis? Obviously, and for reasons already emphasized, no single standard of function can possibly be established, because of the wide variations in different individuals in health. The most that we can do with this or any other functional kidney test is to determine the range of health. This range, after the ingestion of 30 grams of urea, I believe to be approximately represented by the highest and the lowest of the three charts, 5 to 7 inclusive, giving from about 5 to about 10 grams in the highest two-hour excretion period, with a range of total excretion during the first 12 hours of 20 to 30 grams.

Cases with an excretion much below 20 grams should be regarded as of somewhat limited functional capacity for urea excretion, while one-half this lowest limit probably represents serious or even dangerous impairment of functions. It might be mentioned in this connection that the difficulties in the way of establishing a standard for comparison is no greater with this specific physiologic test for one phase of kidney function, than it is with the more general phenolsulphonephthalein test, which, as can be easily shown, does not differentiate between the urea and other excreting functions of the kidneys. The phthalein test in the conventional 2 hours and 10 minutes may vary in normal individuals anywhere from close to 100 per cent. down to about 50 per cent. In other words the proportion of the lowest to the highest range in health may be about as 1:2. This is equally true of the urea test so far as highest and lowest bihourly outputs are concerned, and is simply an expression of the wide range of normal functional capacity already emphasized. To say that it is not an obstacle in the interpretation of any functional test is absurd. It is, however, equally absurd to reject the valuable information which functional tests can furnish, simply because they cannot be reduced to a rule of three. To be safely guided by them requires clinical judgment without which any laboratory aid to diagnosis is a delusion and a snare.

I do not think it is necessary to comment at length upon charts 8 to 14 inclusive, which represent various degrees and phases of renal disease, with the exception perhaps of No. 13. This is from a case of diabetes, and shows a rather large urea output which is quite in harmony with clinical findings in diabetes, with an interesting fall in the third bi-hourly period and a subsequent rise in the fourth; and No. 14 which gives with a normal high point, a sustained excretion above 3 grams for 12 hours, indicating that the kidneys are working at pretty high pressure during that time to unload the excess of urea. No. 12 is noteworthy, illustrating a not infrequent prolonged drop in functional activity followed, 10 hours after the ingestion of the urea, by a second rise equal to the first.

In the following table is presented a comparative study of the phthalein and urea excretion:

COMPARATIVE STUDY OF RENAL FUNCTION AS SHOWN BY UREA AND PHTHALEIN EXCRETION

| Case No. | Twelve Hours Output | Highest Bihourly Output | Per Cent. of Normal Bihourly Output | Per Cent. of Phthalein 2 Hours 10 Minutes |
|---|---|---|---|---|
| 231 | 12.87 | 3.5 | 35 | 18 |
| 391 | 22.16 | 5.5 | 55 | 54 |
| 9 | 16.40 | 4.0 | 40 | 25 |
| 367 | 16.51 | 3.8 | 38 | 64 |
| 596 | 15.25 | 3.6 | 36 | 16 |
| 719 | 10.25 | 2.4 | 24 | 9 |
| 533 | 23.16 | 5.7 | 57 | 45 |
| 631 | 12.37 | 3.9 | 39 | 21 |
| 686 | 35.35 | 7.5 | 75 | 25 |
| 603 | 17.67 | 3.6 | 36 | 50 |
| 700 | 24.50 | 6.7 | 67 | 30 |
| 926 | 20.65 | 6.0 | 60 | 28 |
| 289 | 13.51 | 3.2 | 32 | 7 |
| 129 | 11.75 | 3.5 | 35 | 33 |
| 292 | 15.72 | 5.4 | 54 | 55 |
| 378 | 16. | 3.7 | 37 | 40 |
| .... | 32.05 | 6.2 | 62 | 47 |
| 855 | 21.75 | 5.4 | 54 | 43 |
| 511 | 22.1 | 5.8 | 58 | 25 |
| 929 | 23.05 | 5.4 | 54 | 38 |
| 65 | 19.9 | 5.1 | 51 | 46 |
| 337 | 25.5 | 9.6 | 96 | 48 |
| 118 | 18.3 | 4.2 | 42 | 32 |
| 449 | 11.7 | 2.9 | 29 | 21 |

The percentages are placed in parallel columns, the phthalein percentage indicating as usual the proportion of the entire 6 milligrams excreted in 2 hours and 10 minutes, while the urea percentages indicate the proportion of the highest output shown in the case to the high normal of 10 grams in 2 hours. A careful study of this table will demonstrate what I have repeatedly emphasized, that the functional capacity of the kidneys to excrete phthalein is not at all parallel to that of urea.

A word should perhaps be said about the significance and relative diagnostic value of the highest bi-hourly excretion of urea on the one hand, and the 12-hour output on the other. It seems perfectly obvious to me that the real maximal capacity of kidney function is best expressed by the highest excretion in a limited time—2 hours being the time chosen in this investigation. On the other hand the quantity of urea excretion of which the kidneys are capable in a considerably longer period of time —say 12 or 24 hours—might appear from certain points of view more important. As a matter of fact, a pair of kidneys with relatively smaller functional capacity by working constantly, at the highest possible rate of speed, possibly stimulated by morbid irritation, might do in 12 hours a larger actual volume of work than another, which, for some reason, while capable of doing much more, does not maintain continuously so rapid a rate of excretion. For instance, in chart No. 5 the highest bi-hourly rate is 9.6; the twelve-hour excretion 25.5 grams. In chart No. 13 the highest bi-hourly output is 7.5 grams while the twelve-hour output is 35.35 grams.

Illustrations of a similar character might be added from these and other unpublished charts. The same feature of long sustained maximal functional work on the part of damaged kidneys is prominently and most convincingly shown by Albarran in the work upon which his polyuria test is based. A kidney, *e.g.* which is badly damaged, may, as he clearly shows, be excreting more water under ordinary conditions than a perfectly normal kidney with a functional capacity many times greater. When the extra demand is made upon it, however, it may not do much more than before, while on the other hand the normal kidney may respond by a many times multiplied excretion.

It appears to me that the capacity of the kidneys to excrete urea, when a large extra demand is made upon them should be viewed somewhat in the same light. Albarran's work was, of course, surgical and his findings were commonly checked by operative procedure, a sort of check which is obviously impossible in the routine kidney work of the internist. Albarran says distinctly that in a large surgical practice he has never once been deceived by this principle of interpretation, and we may well learn such lessons and draw such inferences, from his work as we can with due reserve and caution, recognizing the different aspects of the problems which confront the surgeon and internist.

*Conclusions.*—1. It is now fully established that the functional impairment of the kidneys may be limited, or at least more marked, with reference to certain classes of waste products. There may be, *e.g.* (and these are the most important groups) varying degrees of renal block for urea, chlorides, or water.

2. This makes it extremely important from a therapeutic point of view to differentiate between the various types of renal block because the dietetic treatment of chronic kidney disease, by far its most important phase, can be intelligently directed only with full knowledge of this differentiation.

3. This differentiation cannot possibly be made by routine laboratory methods or by the phenolsulphonephthalein test because, as clearly shown in the above table, there is no parallelism between the capacity of the kidneys to eliminate phthalein on the one hand and urea on the other. The parallelism between phthalein and chloride elimination I have not investigated.

4. This differentiation can best be determined by surcharging the blood with the different substances in question and determining the rate of excretion of each, first over a brief period of time, *while the blood remains heavily surcharged*, and again over a longer period to determine the duration of time required to depurate the blood of a morbid excess.

5. The permeability of the kidneys for urea can be determined with great accuracy, in the absence of marked gastric stasis, by the ingestion of 30 grams of urea, according to the method described in this communication and furnishes a scientific basis for the regulation of the proteid intake.

6. While this method is easily within the reach of any physician who can make a determination of urea by the simple and inexpensive Doremus apparatus, which is sufficiently accurate for such an investigation, yet it is too laborious and time-consuming to be used as a routine method (for which the phthalein test is sufficient), but has a very high value in properly selected cases, in which, especially for therapeutic purposes, it is advantageous to know the type of renal block present.

7. The capacity of the kidneys for chloride and water excretion can, and in suitable cases, should be determined by similar methods, although the interpretation would be much more complex.

I desire to acknowledge my indebtedness to Dr. M. F. Porter, Jr., and Dr. B. M. Edlavitch for their assistance in this work.

# THE USE OF PINEAL GLAND IN THE TREATMENT OF CERTAIN CLASSES OF DEFECTIVE CHILDREN.*

By WILLIAM N. BERKELEY, A.B., PH.B., M.D.,
NEW YORK.
ATTENDING PHYSICIAN AT THE GOOD SAMARITAN DISPENSARY.

It is now over three years since Prof. C. L. Dana of New York telephoned to me at my office late one evening and said: "Dr. Berkeley, I wonder if I could get you sufficiently interested in the function of the pineal gland to undertake some research work on the subject?" I was a little appalled at such a suggestion touching one of the most mysterious organs in the body, and said: "You mean the hypophysis cerebri, do you not?" "No," he said, "I mean the epiphysis, the pineal gland, the conarium; go down to the Academy of Medicine and hunt up Frankl-Hochwart's account in the *Zeitschrift für Nervenheilkunde* of a tumor of the pineal gland in a boy of five and a half years, and see what you think of it." I did so the very next day, and that was the beginning of my interest in the development of the pineal gland as a clinical resource. But I must not fail to emphasize the fact that the original notion of the profit of such a research was entirely Dr. Dana's and that his ripe judgment and conservative advice have done much to bring to the work the measure of success it has met with.

This case of Frankl-Hochwart's is typical of a number that have appeared in recent medical literature, and is one of very great interest—an interest that would have been much more adequate and far-reaching but for the imperfection with which the original account has been quoted. The boy was under observation for a number of months and at the time of his death was conclusively proved to be only five and a half years old. He was as large as a normal boy of 12 or 13, had well-developed pubic hair, and a low-pitched voice. His mentality was also notably precocious; he is said to have asked many questions about the condition of the soul after death, and on another occasion remarked reflectively: "It is odd how much better I feel when I let the other children play with my toys than when I play with them myself."

Clinically the case was characterized by headache, by occasional projectile vomiting, and by choked disc. At autopsy there was found a peculiar tumor of the pineal gland. Microscopical sections of this tumor were drawn and the drawings are published in the article referred to. They have been interpreted by Frankl-Hochwart himself, by Marburg, and by others of the Vienna School as indicating a destructive lesion of the pineal gland. Without being able to offer any demonstrative evidence against this conclusion, and without meaning to question the judgment of Professor Frankl-Hochwart himself, for whom, as an old teacher of mine I entertain the highest respect, it appeared to me not at all impossible that on the contrary the tumor might have been in certain of its parts an adenoma of the pineal gland, involving some increase in its function. After talking this point over with Dr. Dana it appeared probable that if our own supposition was correct the same results, at least in the matter of physical growth, should be produced by feeding the gland to normal young animals, and that if this experiment proved encouraging we might next try the effect of pineal medication upon physically and mentally retarded children. This in brief was the guiding principle and aim of our work since that time.

After we had spent a winter in some preliminary work the Trustees of the Rockefeller Institute very kindly extended some aid to what had proved a rather expensive undertaking, and a long and laborious report on the whole subject was published in the Medical Record nearly a year ago. It has been the complaint of many that this article, by reason of its very technicality and length, was unreadable by many busy professional men who might be specially expected to interest themselves in trying out the new remedy. It seems therefore worth while to set forth more briefly and directly what the research has actually accomplished.

I shall speak of the form of the gland used as a medicament, then of the results with young animals, then finally of the clinical facts in the case of certain classes of retarded children.

First, as regards the gland, we began with calves' pineal, but it was found after a few weeks' work that to obtain these in any quantity was too difficult a proposition to be practicable. Since that time we have used exclusively the glands of young bullocks. The fresh glands were rapidly dried, mixed with milk sugar, and put up in capsules, each capsule corresponding to 150 pounds of bullock,—live weight. This is a physiological dose and enables one to avoid the chances of error (increased fibrous tissue, calcareous deposits and other anomalies) affecting the weight of the crude gland. These capsules are not unduly expensive considering that the dose is small. They may now be had, correctly prepared according to my formula, in several New York pharmacies. The ordinary dose for a child of 25 or 50 pounds' weight is one or two capsules a day, best after eating. For children who will not or cannot swallow the capsule whole, it may be opened and the powder given directly or upon a bit of buttered bread. The gland has proved uniformly harmless to the stomachs of many delicate children; only one or two doubtful instances of indigestion ensuing upon its use have been reported. As the gland usually contains no very dense fibrous tissue and no fat, this method of administration seems to me much the best, and I do not recommend any preparation purporting to be an "extract."

In respect of the work with young animals, guinea-pigs, kittens, and rabbits were used. The experiments have covered nearly two years in time and have gone far enough to produce some interesting results. Of eight half-grown guinea-pigs under observation for five weeks, four subjects gained 36 per cent. and four controls gained 25 per cent. in weight. Of a dozen small kittens the subjects outgrew the controls rapidly in activity, size, intelligence, and resistance to intercurrent disease. The best control, beginning with a weight of 11 ounces, gained four ounces in two months and a half. The best subject, starting with a weight of 12 ounces, gained 12 ounces more, doubling his weight. All were fed alike. The medication was fresh gland—one calf's gland per day for each subject, or a measured amount of nucleoproteid solution in milk.

Of ten small rabbits of varying color and size, under observation for five months, five were fed on the pineal capsules described above; one died (accident), and the four survivors, weighing *in toto*

*Abridged from an informal account given recently before the Society of Internal Medicine, New York City.

at the beginning of the experiment 99 ounces, gained in the period mentioned a total of 192.3 ounces, or an average of 48 ounces per rabbit. Of the five controls two died, and the three survivors at the end of the five months had gained in all 107.4 ounces, or 36 ounces per rabbit. The subjects were beautiful specimens—clean, active, fat, and salacious—and their growth was remarkable. One of the smaller ones trebled his weight exactly.

I come finally to our experiences with defective children. Here there first arises of course the natural, and, unfortunately, the very difficult question, "What is a defective child?" The term is applied nowadays in medical treatises to a vast number of clearly different conditions. Outside of the congenital half-human monstrosities, the cretins, and the mongols, the porencephalics, the monoplegics, and the rest, there are many mentally deficient children in whose physical make-up, outside the brain, nothing abnormal can be discovered. They have well-shaped heads, normal eyes, symmetrically perfect limbs, and an excellent digestion. They often grow rapidly and have excessive strength of muscle. In these cases it appears that the cerebral *chemistry* is alone at fault, and that if we had but "the key to the lock," the "proper spark-plug for the motor," all might go well. The question is further complicated in the case of the high-grade "moron" by the curious fact that he progresses normally up to his eighth, or tenth, or twelfth year, as the case may be, and then stops, the cause of his arrest being as mysterious as are the operations of the cerebral forces when normally in action. Moreover nearly all such patients—the physically negative ones—are so different from one another in their mental deficiencies that thus far no definite classification has been possible for them. Some can do simple mental operations proper for the normal child a few years younger than themselves; some, on the contrary, at six and eight years of age are still as helpless and untidy as babies.

It has long been supposed since Horsley's classic work on cretinism that others of the internal secretions might be at fault in unclassified cases of mental deficiency in children. But experiment has been disappointing, both because the preparations of the glands of internal secretion have until recently been notoriously unreliable, and because in the cases chosen for experiment the "key did not fit the lock."

With these bewildering facts before us there seemed but one way out of the difficulty—to give the remedy a fair trial on a large number of cases. Among these there were to start with a few cases of simple physical dwarfism with good mentality. These I presently left out of the investigation entirely, as I became convinced they were subjects for pituitary medication only. The pineal gland has now had a more or less fair test on nearly 100 mentally defective children. A large majority of these were without physical stigmata. They belonged in general to the unclassified group of cases I have already described. The following brief account discloses some remarkable results, and indicates in a general way what patients it will be worth while to make the experiment with in future.

I will take up the negative side of the work first. No experiments upon cretinism were made. A valuable specific medicine for this disease is already at hand. The gland was tried on one amaurotic idiot 18 months old; there was no definite result. As a matter of completing the record the gland was tried—always with negative results—upon a few congenital idiots of 8-15 years of physical age. I also found as far as our experience went that little or no response could be elicited *in mental defectives* of *any class over* 15 *years of age.* In respect of two mongols under my treatment for several months it was my impression that both made some progress, but as they might have been expected to make a certain degree of progress anyway I had no satisfactory control for them, and I shall have to leave it for the future to determine what pineal therapy can do for the medium and high-grade mongolian idiot. I doubt whether anything will ever help the low-grade mongol.

Turning now from the gloomy side of the question, I may mention finally, in brief, some of the case histories that appear to have reasonably justified the research.

At the Training School at Vineland, N. J., some impartial and exactly scientific tests of pineal gland were made by Dr. Henry H. Goddard. A four months' test was arranged. Some twenty-five subjects and twenty-five controls started upon the experiment; twenty-one subjects and fourteen controls finished. The criticism will at once be offered that the use of a control in such a case is impossible, no two defective children being ever exactly alike. However, each child was grouped with the child or children nearest him in heredity and mental age (Binet tests), and Dr. Goddard is of the opinion that by testing more than a dozen couples or trios of children in this way gross error may be safely avoided. All the children were under the regular dietetic and educational routine of the institution. Of the subjects, several were congenital idiots, and these, as was anticipated, made no progress. But fourteen of the others made a gain, and the average, .65 of a year, was twice the normal, and more than twice the progress of the control children in the same period. Some of the subjects advanced .8 of a year; one advanced 1.8 years. This child's teacher, who had not heard of the pineal gland experiment, came voluntarily and asked what new medicine the child was getting—that his progress was quite unusual.

There was another group of backward children at Public School 12, Jackson and Henry streets, New York, with whom the treatment was kindly undertaken by Miss Carol Young (Mrs. Startzman), the teacher in charge. Mrs. Startzman is herself a graduate of the Teachers' Training School at Vineland. Here the practical difficulties were much greater than at the school first mentioned. After struggling with many careless and indifferent mothers for a while Miss Young finally hit upon the expedient of keeping the capsules at school and giving one to each pupil as directed (the parents' consent having been obtained) on school days only, medication being omitted altogether on Saturdays and Sundays. This scheme worked very well, and a majority of the children tested—about sixteen in all—made more or less response; those well marked by organic defects were a uniform exception. The period of trial was five months.

All these cases have been exhaustively written up in the formal report previously referred to, but I may mention again as examples of what may be accomplished with pineal medication the cases of Hannah T. and Rose R. For brevity's sake only the essential parts of the case-histories are given here.

Case XIV.—Rose R., P. S. 12 (Miss Carol K. Young).

Weight, 60½ lbs.; height, 31½ in.; age, 9 yrs. Date first visit, November 11, 1911. Family history: Mother, 43 yrs. old; one miscarriage (2 mos.) 6 yrs. ago; 5 boys, 16, 15, 12, 5, 22 mos.; all healthy mentally. Previous personal history: 9 mos. child; mother in labor 16 hrs.; no forceps; walked 14 mos.; talked at 15 mos.; meningitis at 17 mos.; in bed 10 wks.; convulsions then; not since; been in class for defectives at P. S. 12 for 3 yrs.; making very slow progress. Status præsens: P., 80; R., good; T., normal. Color of skin: Healthy; rosy and robust appearance; bright expression. Special senses: Eyes now fitted with glasses; seems to have good vision. Treatment: Pineal capsules, 2 per day. December 30, has been away several weeks; grown ½ in.; prescribed 2 caps.; Miss Young reports favorable progress. Again Miss Young writes, February 26, 1912: "Began treatment in November. On account of illness in family did not go regularly. Her improvement has been notable since she began taking the gland. Before her lessons seemed to be a burden to her and now she seems to enjoy them. Does not fatigue so easily. She has always been very nervous and could not concentrate for any length of time. She does not get these nervous spells as often as she did, and sticks to her work until finished. She spells well—for her—recognizes words much better and reads much better than she did. There has also been improvement in number work. She knows her tables fairly well and can add, subtract, and multiply by one figure. She has made two sofa cushions and two aprons in school since taking the gland, and that is a great deal for her to accomplish, as she is so slow. She is now monitor for the lunch table, and tries to do it *well*. Six months ago I wouldn't have thought she could ever be as good as she is. Am sure her improvement is due to pineal gland. I hope to return her to the grades in June."

Case IX.—Hannah T., P. S. 12 (Miss Young). Girl 9½ years, weight and height about normal for age. Family history negative so far as it could be got. Child was born at term; labor precipitate; no instruments. Well until 5 mos. of age, then had "convulsions." Has had pneumonia and bronchial trouble several times. Color of skin: Fair. Wears glasses. Has been operated on four times for adenoids and tonsils. The thorax is rickety. Organs negative. Has been mentally retarded for a number of years past. Child got two caps. of pineal gland per day regularly from the 1st of January, 1912. On Feb. 26 Miss Young reported as follows: "This child has improved most of all since taking the gland. She began the first of the year, and has shown a decided improvement ever since. A year ago she could not write a word or sentence without help. Now she writes simple sentences in language without any help. In September she could not spell a word. At the end of January in a spelling review of 40 words she spelled 38 correctly. She reads much better than she did, and can now do simple combinations in number. She has always tried very hard to sew, and since January 1 has completed a sofa-cushion in cross-stitch embroidery. I am very proud of Hannah's improvement."

Benny W., a clinic case in my own care, also did very remarkably:

Case XXI.—Benny W., New York (Dr. Berkeley).—Weight, 42½ lbs.; height, 43½ ins.; age 7 yrs. Family history: Father not seen, but reported healthy; age not ascertained. Mother, 33 yrs. old, of excellent appearance. There are three other children, all boys, aged 13, 11 and 5 yrs. respectively; all these were seen, and all were normal, or even precocious. Date of first visit: June 15, 1911. Personal history: Child born without incident, but was always backward. Did not walk till three, and has never said any connected or intelligent words. He can repeat short sentences after his mother, but this appears to be true echolalia, as he gives little appearance of understanding what he repeats. Cannot buy a pennyworth of candy. Is said to wet himself habitually, and soils himself several times a week. Mother professed herself in despair about the child and willing to do anything for his relief. Physical examination entirely negative, except that the boy is cross-eyed (1.50 D. hyperopic astigmatism). He has no physical stigmata, but presents a vacant animal face, smiles inanely and drools continually. His muscles and skin are relaxed, and he stands with bent knees and bowed head. He is said to be very "nervous," and cries a good deal, which might be attributed to the quantity of coffee he has been allowed to have. The treatment of this case consisted solely in the giving of pineal gland. His eyes were fitted with glasses, but these he soon refused to wear, and the treatment was continued without them. June 26.—Weight 43¼ lbs. Looks brighter. Mother thinks his mental condition much improved. Has gone to toilet alone and not soiled himself at all this week. Has said some connected words; cried because younger brother was dressed before him (had never noticed this before). July 3.—Mentality still improving; talks a great deal more. Weight, 41¾ lbs.—a decline due possibly to the hot weather. July 10.—Weight, 42 lbs.; intelligence rapidly increasing; yesterday asked his mother for the key to the toilet; has entirely ceased to soil or wet himself. Height unchanged. Nurse and assistant at the Clinic remarked upon the patient's improved appearance. Aug. 14.—Weight, 44¼ lbs.; height, 44½ ins. Understands and answers simple questions, and has acquired between fifty and one hundred words. Facial expression transformed. Habits entirely correct.

Without going any further into details, I think enough has been said to justify in some measure the faith that is in us that pineal gland is going to be a remedy of great value in many cases of retarded mentality in children, and I do not think it detracts in any degree from the value of the research to admit freely that we have made only a beginning.

The cases so far showing improvement have been so different—no similarity of facies being notable, or of cutaneous nutrition or of mental condition—that the search for a definite type of *hypopinealism* or *apinealism*, has so far been elusive. Possibly my case of Benny W. (above related—Case XXI) is one of hypopinealism, but more cases must be studied by a larger number of observers before one can be sure of his ground in making generalizations of this sort.

That we "do not know just how the medicine works" is a reproach to which the plea of guilty must also be entered. I am personally convinced, in view of the relative smallness of the gland, that its secretion is simply a ferment, facilitating nitrogenous exchange in the cells of the brain. But I have not proved this statement; it is merely a hypothesis.

Reaching further into collateral lines of research, the question arises, If the gland accelerates the sluggish action of the brain in the retarded child, will it not perhaps also serve to arrest or delay certain cases of premature breakdown of the mental powers in old age? To this branch of the subject I have given a good deal of time latterly, and I have been quite astonished to see what the gland can sometimes do. It will not reduce high arterial pressure nor soften hardened arteries, nor smooth out crumpled heart valves; but in cases of premature mental failure without a distinct organic cause, it has proved of great value in about a dozen patients with whom it has received a fair trial. Some of them decline positively to be without it, and judging by their cheerfulness and mental activity while under its influence, I must conclude that it definitely stimulates the aging brain to the faster chemistry of younger days.

Finally, one must continually bear in mind, when caring for defective children, that their progress is slow, that the medicine must be systematically given for from four to six months, and that the coincident educational training must be accurately adapted to their precise mental age. The mind even of a healthy and normal child may run to weeds when no effort is made to save him from neglect.

133 East Sixty-first Street.

# LUES—THE INCORRIGIBLE.

By WILLIAM P. CUNNINGHAM, M.D.,

NEW YORK.

LECTURER ON DERMATOLOGY AT FORDHAM UNIVERSITY; CLINICAL ASSISTANT, NEW YORK SKIN AND CANCER HOSPITAL; ASSISTANT PHYSICIAN, HARLEM HOSPITAL, DERMATOLOGICAL DEPARTMENT.

We have shot our last bolt, made our last bombastic boast, exploited to the limit the patented panacea of the new Apostle Paul, and we are still confronted with the unpalatable truth that in lues our medication offers no assurance of success. After a faithful adherence to the prescribed term of treatment, the luckless luetic who is entering on the long martyrdom of locomotor ataxia, might well exclaim in the manner of the Bard of Avon: "A pox on both your houses, salvarsan and mercury." It is demonstrated that the mercurial treatment does not prevent the so-called parasyphilides. Paresis and tabes, the hideous offspring of this Gorgonic plague, seem to appear indifferently to those who have and those who have not striven to avoid them. It is admitted that the salvarsan treatment is equally ineffective, because by the latest inspired utterance of the prophet of the new dispensation, it is necessary to have recourse to mercury for two years after having undergone his get-well-quick injections. It is clear that nothing more is to be expected from it than from the mercury. Therefore it is not wide of the truth to declare that we have no preventive of these deplorable consequences. Nobody will deny that salvarsan exerts an influence on the manifestations of syphilis, that is in some instances very remarkable. No fair-minded observer will deny that mercury hypodermatically does the very same thing. In fact, it is not uncommon to see routine medication by the mouth accomplish speedy and often surprising results. It is all a question, no doubt, of the relative resistance of different patients to the luetic infection. Some need much help to fight it off and some need very little. But after the obtrusive lesion has been cleared away, even after the full course of treatment decided upon for the elimination of the contamination from the blood, we have simply fought a drawn battle. The outer works may be swept clear of the enemy, but the citadel is still in its hands. And no assurance can ever be had that that citadel will not be indefinitely held and eventually destroyed by the enemy. The brain and cord are never safe in any syphilitic. No matter how faithful he may have been in following out instructions, no matter how abstemious and well ordered may have been the manner of his life after acquiring the infection, he is liable in a few years to be stricken in the center of intelligence or locomotion, and pay the price of capital punishment. And to illustrate the inconsistency and inscrutability of this mysterious disease the careless patient who has had no sustained medication and has gone cheerily on his way, indifferent to possible developments, very frequently lives to a ripe old age in full possession of his faculties. And to further emphasize its eccentricities, how often have we seen the bountiful progenitor of many abortive and infected offspring, present to the world a vigorous personality, "sans tache et sans reprôche"? To the cynic it would appear that in generously endowing his progeny with a wealth of spirochetæ, he had in some manner reduced the number of his own. These circumstances are familiar to every practitioner. They in no way militate against the wisdom of active treatment, as it is certain that in a given number of cases there will be more casualties among the lax and negligent than among the alert and steadfast. But they do drive home the conviction that we have to do with a proposition of which we do not perfectly understand the terms. We postulate the infection and the reputed remedies and the individual equation. We are perfectly familiar with the first and second, and we do not know a thing about the third. We do not know why our remedies even in moderate doses will give us immediate results in some individuals and fail us utterly in others. We do not know why the patient who has shown no symptoms for several years after the discontinuance of a long and careful course of treatment, will suddenly develop a fibrillary tremor of the lips, a steadily increasing unreliability of memory, and an alteration of disposition tending to the apathetic. If it is possible to safeguard any one against such a deplorable fate this man should have escaped. I can cite the case of a patient who is dying of paretic dementia in a nearby sanatorium, who contracted syphilis fifteen years ago, and who at once began a vigorous course of treatment which was sustained for three years. During that time his habits were exemplary. He gained in health and strength constantly until one day in his exuberance of spirits he declared that he was glad he had contracted the disease as it had weaned him from all his vicious courses and set him on the high road to financial prosperity. This high mark of physical and mental well-being was maintained for twelve years. He married and begat a perfect, healthy child. Without any premonition, without the appearance of a single sign of trouble in the interim, he began to show a change of disposition. He became dull or at times easily excited. He developed a "religious streak." He rambled in his speech and forgot the things with which he was most intimately acquainted. His condition grew so bad that restraint was demanded, and he was transferred to the sanatorium, where after a lapse of a very few months he is slowly dying with his once splendid brain capable of nothing but automatic function. If there is anything in our medication why should a case like that go wrong? A case receiving no treatment whatever could hardly have pursued a more disastrous course.

The title of this paper, therefore, in no way exaggerates the actual status of this steadily growing menace to the health of the community. It will take its ruthless reckoning despite our most determined and best conceived resistance. It is trivial indeed to point to the wiping away of surface lesions and the filling in of ulcerations, and even the rescue of an occasional nose or eye, if we are powerless to prevent the destruction of the central nervous system. It is conceded that we can remove gummatous deposits even in the central nervous system, in time to obviate permanent disability, but that subtle, insidious, insistent devitalization of its delicate functioning elements, giving absolutely no hint of its activity until the paralyzing blow is struck, is utterly beyond the influence of our intensest interference. Therefore, is lues incorrigible. We may bring about a little surface decorum, we may paint the sepulcher a most alluring white, but hidden deep within, and far beyond our reach, is this indeterminate, indefinable and undeterrable force (be it virus, be it germ, or hemic vitiation) mercilessly moving to the overthrow of the struc-

ture. Candidly, in proportion to the whole number of syphilitics, the cases of paresis and tabes and other forms of myelitis are happily infrequent. This may be due to various causes. Many victims are carried off by other diseases before these usually late developments have an opportunity to appear. Doubtless many of the infected possess a strong power of resistance to the encroachment of the spirochete. Possibly contributory causes are in a measure responsible for the centering of the assault upon the brain or cord. For instance, men of active intellect constantly demanding more and more of their cerebral cells, incessantly inciting them to greater functional extremes, are supposed to be more easily reduced to paresis than those whose mental processes are largely concerned in the direction of muscular effort. Perhaps sexual excesses are for a like reason held accountable for the incidence of the attack on the columns of Goll. Whether there is anything worth while in these suppositions, is a very difficult matter to determine, because the testimony is too contradictory and confusing. Exempli gratia, why is locomotor ataxia so much rarer in women than it is in men, when sexual abuse is certainly not a monopoly of either? What male votary at the shrine of Venus ever undergoes the persistent incredible excesses of the prostitute? Yet, taking the cases as they run, the woman with syphilis has ten chances to one in her favor of escaping this complication. Let us go a little further and admit that the few cases of tabes found in women are likely to be in those who have contracted syphilis in wedlock and have not been afflicted with nymphomania. It has been reported by Noguchi that the spirochetæ have been found in the central nervous system in some cases that have come to autopsy, but the spirochetæ have been "sparse." Evidently the destruction of the cerebral and spinal cells can be wrought by a very few of these invaders, or else the technique of finding them has not yet been brought to the requisite point of efficiency. There must be an almost impassable barrier to their entrance into the female neuroglia. The susceptibility of the female to their influence in other situations is a matter of common knowledge. She displays as many cutaneous mucous and parenchymatous lesions as the male with the single remarkable exception noted. It is obviously quite impossible to account for individual susceptibility when we cannot account for the susceptibilty of a whole sex. We know that this exists, but the why and wherefore pass our understanding. The discovery of the cause of syphilis has shed no light upon these curious problems. We have found the specific organism, and it has been of service in corroboration of some questionable diagnoses, but nothing more of practical value has resulted. The Wassermann reaction does not depend upon the recognition of the essential cause, but upon the assumption that there is such a cause tending to arouse anti-bodies in the blood. This valuable test was just as possible of discovery, and would be just as useful and decisive if the spirochetæ had never been born to our admiring gaze. We are just where we were when the accepted teaching was that tertiary syphilis was no longer active syphilis, but an altered condition of the patient's blood tending to the formation of gummatous and fibrous tissue. In other words, we are brought face to face with the fact that these so-called para-syphilides of the ancient nosology, are just as much beyond our comprehension and control as they were before we were startled by the dual discovery of the specific spiral and its numerical nemesis.

It may be objected that discussing the neurological aspects of tertiary syphilis is a peculiar and presumptuous performance for a dermatologist. In extenuation it may be urged that we have so much to do with the other manifestations of this particular preventive of over-population, that we are naturally interested in all of its developments. As we have to advise the patients in the early days of their affliction, it is right and proper that we should possess the completest knowledge of its complications and eventualities. And, if we are to draw the fullest lesson from the sins of others, we must be able to deter the budding sybarite by gruesome predictions of the horrors of luetic infection. To be effective these predictions must be truthful; therefore, they must be based upon a comprehensive grasp of the whole subject. Therefore, it is rational that the dermatologist, with whom most frequently the original diagnosis rests, should be able to discourse fluently upon every possible aspect of the subject. It would be absurd to deny him the privilege of discussing the two most lamentable terminations of this polypragmatic pestilence. If withheld by the limitations of arbitrary specialism, from a consideration of the nervous complications, he might as well be withheld from a consideration of every other manifestation save those on the skin and be reduced at once to the contemptible level of a "beauty doctor." If our ministrations are to be so confined, our business with the patient will consist in keeping his skin clear of unsightly or compromising indications. We are not to warn him of iritis, for here we should be trespassing on the preserves of the ophthalmologist, with which we are supposed to having nothing to do. We are not to warn him of aneurysm, or arteriosclerosis, because we should be running foul of the internist, whose domain for us is ticketed "no thoroughfare." We are not allowed to caution him against the probability of accusatory infantile dyscrasia because that would be an infringement on the inviolable rights of the gynecologist and pediatrist. Under such an interpretation of the distinctive rights and privileges of the various specialities we should have a complete reductio ad absurdum. Per contra, it is reasonable, and therefore right and proper for the original diagnostician to pursue the disease in all of its ramifications, provided he possesses the requisite information for its recognition and attack. The moment that special skill is demanded in any of these correlated manifestations it is his duty to turn the case over to the indicated expert. A long dissertation this on the rights of specialism, and perhaps not obviously to the point, but as the subject of this paper is the incorrigibility of lues, and as that incorrigibility is most clearly manifest in the invasion and destruction of the nervous system, the applicability of the argument is soon apparent.

Demonstrably incorrigible, are we to become callous spectators of its depredations, and make no effort to withstand them? Because up to the present our ministrations offer no assurance of complete emancipation from the horrifying possibilities of this noisome infection, it is not beyond the bounds of hope that that result may some time be attained. And it will never be anything but a hope if we do not fight for its realization. With all the means at our command, no matter how inadequate they are, we must struggle on and ever on to the

light that is vouchsafed to the undiscouraged seeker of the truth. Meanwhile we should turn to good account the grim and solemn fact that with the means at our command lues is incorrigible. To him who has already offered up his lusty manhood upon the altar of concupiscence, and has drawn the blistering, blighting bane of chancrous initiation, it is bootless to emphasize the subject of paralyzing possibilities. The mental depression might drive him into a despairing disregard for all therapeutics, and precipitate the evil we wish to avoid. To keep a patient up to the mark in his attention to his malady it is well to hint that ataxia and tabes often follow improperly treated cases. The pious fraud that careful handling will avert those consequences is admissible as a therapeutic measure to sustain the patient. And, of course, there are other avoidable fatalities which negligence would invite. There are gummata in various inconvenient and threatening situations which we may be able to forestall.

But what of the adolescent coming up to manhood still untainted but seriously tempted by the strange emotions struggling for the ascendancy? To him it will be wise and fruitful to paint in all its terrors the picture of these awful consequences that no medical science can *positively* prevent. Assure him that one indiscretion may bring upon him a train of evils whose culmination may be the asylum or the wheelchair. Here is the point to make the most of the incorrigibility of lues. Din it in, sear it in, compel him to see and be afraid. This is no sermon. This is a treatise on preventive medicine. Medical and social bodies the world over are deeply concerned with the problem of controlling venereal diseases. They would do it by legislation. But their more or less luminous suggestions have to do only with segregation, examination, and other police regulations. And the foul and fetid things will grow and multiply despite all their memorializing and experimentation. Why? Because they are beginning at the wrong end. It is practically useless to try to avoid the consequences of meretricious acts, while those acts are not only tolerated but sanctioned as necessary. If the public conscience tolerates prostitution, and the safeguarding of its patrons, there is a spirit of lascivious license generated among the young which will seek indulgence in secret and devious ways beyond the control of official regulators. The wages of sin will be exacted despite all our shuffling evasions. It is the law of compensation and it will not be denied. Prostitution defies the natural and moral law and no amount of equivocation and regulation will rob the ulcerous thing of its consequences. "What!" exclaims the special pleader for the brothel, "Is not sexual intercourse natural? In what way then does it defy the natural law?"

Yes, indeed, sexual intercourse is natural. And so indeed is its legitimate consequence, maternity. Will you call that intercourse natural where, by one device or another, maternity is avoided? Will you call the use of a condom natural? Did such a thing ever naturally appertain to a man? Will you call withdrawal natural? Will you call the use of a bichloride douche to wash away the semen natural? Will you call it natural for a woman to undergo sexual intercourse a dozen times a day and perform a dozen unnatural acts to escape conception? Is not the whole putrid business, from beginning to end a violation of all that is decent, right, and natural? Is it not certain to breed far in excess of all the efforts at misguided control the terrifying evils of blasted bodies and blighted minds? But what shall we do with the rising passions of the young? Marriage as soon as practicable. Until then self-restraint. Self-restraint is not possible? Oh, yes it is. I heard Edward L. Keyes lecture on this very point on one occasion, and he taught that the sexual function suffered no diminution by enforced inactivity even for long periods. We are compelled to control our other passions. We cannot indulge the passion of anger every time the inclination seizes us. We know that if we do we are liable to get our heads punched. Fear may be overcome. Timid men have developed into good soldiers. Decent men do not take advantage of defenceless women even with the passion of concupiscence goading fiercely. In the sacking of towns, officers, who are men, have fought to prevent the violation of women by other men. Self-restraint is possible, you see. But self-restraint is not taught in sexual matters as it is in other matters. It is indulgently conceded that the sexual pull is not to be resisted, but the same allowance is not made for the influence of anger or of fear. Consider, too, that whereas sexual laxity is permitted to the male it is absolutely denied to the female of decent communities. The female exercises a discreet and efficient self-restraint. Fear of consequences may be the determining cause. It is a wholesome fear because the consequences to the female of one lapse from continence may be speedy disgrace. Convince the young men that malignant consequences will follow the yielding to their unbridled lust and you have the same cause operating to deter *them*. The retort is made that sexual desire is in the very nature of things uncontrollable and that all the warnings ever uttered or possible of utterance will fail to swerve men from its gratification. As shown above, this is absolutely false for one whole sex, and for decent well-balanced members of the other. There are considerations outweighing the influence of sexuality. The self-respecting husband whose wife is ill will hold himself in leash. Is every husband whose wife is far advanced in pregnanacy, to be suspected of illicit intercourse? And if men can control themselves from abstract considerations of honor, is it unreasonable to believe that if properly educated they will control themselves for the preservation of life and reason?

This abstinence is not a life sentence as it is in certain religious communities. It is simply a reasonable delay in the gratification of a natural desire until it can be accomplished with decency, honor and safety. Remarkable, also, is it not, that this irresistible urging of the sex appetite can be readily enough kept in subjection when the victim has acquired a gonorrhea, a chancroid, or syphilis! Strange indeed that it cannot be mastered to *avoid* these diseases as well as to cure them. The whole argument in favor of the early indulgence of this appetite is a piece of special pleading founded upon a situation that has been created to justify it. Men have attributed an overwhelming force to their lust because they wanted an excuse to indulge it. Having full control of the law-making power, they have legislated in favor of their own depraved impulses and against those of their sisters. Law and custom punish the transgressions of women and condone those of men. The rake of twenty-five who has indulged himself with numberless women since the dawning of concupiscence, care-

fully selects a girl for his wife of certified virginity. Like Caesar's wife, she must be above suspicion. If it was impossible for him to subdue his natural inclinations until he contracted marriage, how does he suppose the girl has performed that miracle? And if hundreds of thousands of women perform it every day it is not much of a miracle anyway. Viewed in this light the hypocritical pretense of the male contention is seen in all its pitiful weakness. The male yields because he wants to and because he thinks it is reasonably safe. It should be our business to teach him that it is not reasonably safe. The incorrigibility of lues should be shaken before his eyes as a warning of the penalty he may have to pay for his sordid pleasure. In no other way except by reforming the individual voluptuary can we eliminate venereal disease. As stated above, this is not a sermon, but a treatise on preventive medicine. Not one word has been said upon the moral aspect of sex sin. The whole burden of my argument has been the physical consequences thereof. If these are persistently pictured to the minds of our youth, and if sexual indulgence is shown to be something perfectly controllable when honestly attempted, the work of limiting venereal diseases will have been incalculably advanced.

If we are to admit the impossibility of man's dominating his passions instead of his passions dominating him; if we are to admit the necessity of the continual sacrifice of female victims to the Moloch of his relentless brutality; if, for the momentary gratification of a libidinous orgasm, women must be held in the hideous bondage of professional prostitution; if, in order that men may live in satiation, women must rot in degradation: then let us cease to prate of the prophylaxis of venereal diseases, and recognize the futility of attempting to evade these compensatory sequelæ. There is an old, trite aphorism that "those who dance must pay the piper." If men will dance to the moans of outraged virtue, they will pay in the coin of idiocy, ataxia, and premature death.

323 West Fourteenth Street.

## THE PASSING OF THE STOMACH TUBE.*

By JEROME MEYERS, M.D.,
ALBANY, N. Y.

All things wax and wane. Pretty theories have their day for a few years, then grow dusty in long-forgotten books; pet practices work the salvation of the race, then cause a smile at their lost popularity. Time scorns the untrue and experience mocks the unproved. And this is all very true in present-day medicine. No longer dominated by a Hippocrates or a Galen, it now, collectively and individually, experiments, observes, and thinks for itself. It is explorative, it is critical, it is judicial. The chair of the metaphysician has given place to the stool of the experimenter, the elixir of life is forgotten in the study of life, the hands of a king are rudely supplanted by the cleaner and more knowing hands of the surgeon. There are in medicine of today three great forces, each constantly aiding and checking the others, experiment, practice, and reason. The laboratory opens new vistas for diagnosis and treatment, clinical observation augments and makes practical the former's findings; not uncommonly they clash, and it is here that medical reason must operate, and with the power and sharpness of mental training separate the false from the true, the medically valuable from the unimportant. Thus are reliable diagnosis and consistent treatment attained. The indiscriminate use of arsenobenzol as a cure gives way to its careful administration as a remedy in conjunction with mercury or potassium iodide. The unyielding restriction of carbohydrates in diabetes submits to a more tolerant diet. The unlimited dosage of nitroglycerin in hypertension is even now declining to amounts more consistent with the well-being and safety of the patient.

The evolution of medicine has been marked by the use and abuse of drugs and methods; and it is not infrequent that their overuse has resulted in an unwarranted disregard of the intrinsic worth and advantage of such drugs or methods. First recommended in 1879 by Kussmaul for therapeutic use in dilatation, the stomach tube was applied two years later by Leube in the first efforts at the estimation of the time and degree of digestion. Some years later the Boas-Ewald test-breakfast established itself, and it was then that the various gastric conditions gradually unfolded themselves and took definitive shapes. And in the three or four decades of the stomach tube it may have suffered some abuse, both as a therapeutic and a diagnostic instrument. So, for some time it has seemed well to look at this question, when should a stomach tube be passed, how should it be passed, and whether its use or its value is passing.

The question of passing the tube, whether it be for diagnostic or therapeutic purposes, rests on two prime considerations, the need and the possibility. That there may be urgent need in poisoning or serious dietary errors is self-evident. Outside of these more acute conditions what is the need of a stomach tube? There is the same need as there is for a speculum in gynecology, or a laryngoscope, or a cystoscope. A thorough general and abdominal history, in which each question is part of a purposeful cross examination and each reply a possible clue to a correct diagnosis, followed by a competent general and abdominal examination, will in a large percentage of cases give at least a tentative diagnosis. But as an honest suspicion of tuberculosis of the kidney may give way to certainty with the cystoscope, so an honest suspicion of achylia gastrica, or ulcer, or carcinoma may be certified by the stomach tube. It should be passed whenever we are not positive of a diagnosis. Medicine is nothing but an infinite attention to detail. And nowhere is this more true than in the diagnosis and treatment of abdominal diseases. Here diagnoses must be made often by exclusion, and every fact may be valuable. Every single patient and every single disease should be treated individually, and this can be done only by complete and painstaking investigation. I believe that the therapeutic success in the treatment of gastrointestinal diseases depends on the individualization of each patient, not to treat all patients, even with similar diagnoses according to one pattern. The gastric, hepatic, and intestinal functions are so intimately related, yet not infrequently so affected, that lack of knowledge of the condition of one nullifies any treatment that is directed toward only one of them. Either abdominal diagnosis must be complete and rational, or else it is of little value, and therapeutics will prove it. Incomplete and incompetent diagnoses of gastrointestinal diseases are worse than none at all; they usually result in an attempt at symptomatic treat-

*Read before the Albany County Medical Society, November 12, 1913.

ment; the basic pathological condition is unthought and untouched, and soon the patient is the worse for loss of time. No man, however experienced, can diagnose every abdominal case in 5 or 10 minutes; it is a physical and mental impossibility, and must lead to improper diagnosis and treatment. It is often a matter of hours and days, not of seconds and minutes. Probably those who scoff most at the stomach tube are those who use it least, who realize least the necessities of thorough examination within the abdomen, and who cut all gastrointestinal diagnosis out of the same cloth of intestinal indigestion, or gastritis, or ulcer, or whatever else their idle fancy may be. The use of the tube in the diagnosis of gastrogenous diarrhea or constipation, of colitis, of gastric, or duodenal ulcer, or carcinoma cannot be questioned. But even here medical reason must rule. If a diagnosis can be made from the history and physical findings, so much the better; if a diagnosis can be made from the stool as may be done in ulcer, or cancer, or achylia gastrica, in conjunction with other symptoms and findings, so much the better; it is no great pleasure for the patient or the physician to pass a stomach tube. It may be wise at times to delay the use of a tube and depend on a subjective diagnosis, and try the consistent therapy; if the symptoms do not yield, the tube can then be used. But if there be any suspicion of cancer, whether the patient be at the dangerous age or not, the neglect to study the gastric contents is as reprehensible as the delay in removing suspicious nodules from a woman's breast. And it is just here that the man who does not believe in the stomach tube may learn to his sorrow that it may have taught him something. To the complete physician or surgeon nothing in medicine is alien; it is just this spirit of disregard, of nihilism, that renders the earlier diagnosis of gastric carcinoma difficult. The use of the *x*-ray may at times be substituted for a tube and may be of large value, but it must be remembered that the *x*-ray gives mostly an anatomical diagnosis and that it is only from a study of the history and various gastrointestinal tests that we can learn of the functional integrity of the digestive tract. I have recently seen two cases of multiple chronic ulcer of the stomach and duodenum, in both of which there was a complete absence of hydrochloric acid. *X*-ray plates showed the anatomical form of the stomachs and corroborated the diagnoses already made from subjective and objective findings, but the *x*-ray could not tell the complete lack of HCl. It may seem strange to prescribe HCl in ulcer, but then patients seek relief from unpleasant symptoms, and with *x*-ray pictures alone, they might be disappointed. The *x*-ray especially in gastric and duodenal work is largely an adjunct and a most useful one when necessary, but it also can be abused; surely cases of simple ptosis, uncomplicated cases of gastritis and ulcer, of colitis, of cholecystitis do not require *x*-ray plates for diagnosis, but rather a sensible examination of the present and causative conditions.

As regards the therapeutic employment of the tube, there can be no question as to its value in acute poisonings, acute dilatations, serious dietary errors, postoperative ileus, pyloric stenosis with stasis, ulcer or gastritis with large accumulations of gastric juice or mucus. But in the more ill-defined cases there is danger of abuse. Lavage is a legitimate procedure when indicated, but may be easily overdone, and probably many a case of simple ptosis, or a gastritis with little mucus, or a nervous or a psychic disturbance has been subjected to unnecessary discomfort, when a proper investigation and a proper diagnosis and treatment would have been of more lasting benefit. The basic condition is the important consideration, and undoubtedly the use of HCl, or an alkali, or belladonna, or lactic acid bacilli, or the drinking of the proper saline water, or an abdominal belt, or rest, or a generous diet, or an appendectomy, or a cholecystotomy, would have had a more lasting effect than the inflow and outflow of a little water that not infrequently returns as clear as it went in, if it returns at all. And even in stenosis with dilatation it would be just as rational to put the stomach completely at rest either by rectal alimentation as long as possible, or still better, to use the duodenal tube for ten or twelve days so that the stomach receive nothing in the way of food or drink.

How should a stomach tube be passed? The only way to pass it is to wait until you know all the history and physical conditions. It would be very unpleasant to rupture an aortic aneurysm, or to pass through an esophageal diverticulum into the mediastinum, or to tear a varix due to hepatic cirrhosis. If there is any question as to serious bleeding in the stomach, I believe it is wise to examine the stool first for evidence of blood, and then pass the tube if necessary, having explained conditions to someone connected with the patient. If the tube can be passed, there are two rules; pass it as comfortably as possible, and get out as quickly as possible. Twenty to twenty-five cubic centimeters of stomach contents are fully sufficient for all tests. Our aim is to examine the stomach contents, especially for acidities and blood and microscopic elements; when we have 20-25 c.c. we have sufficient for these tests and any other special test; it is well to withdraw the tube, as it is more pleasant for the patient than trying to obtain every last trace. We can tell from the microscopic appearance and examination whether there is great supersecretion or retention. Washing out the stomach after obtaining as much stomach contents as possible would seem of little diagnostic or therapeutic value, unless no contents have been obtained, or unless there is some special indication for lavage. It lengthens unnecessarily a period of unpleasantness for the patient.

If the patient takes the tube badly, it is the better part of valor and medicine to be satisfied with even 5 or 10 c.c. and to do the tests most important in that special case with such an amount. Much of the difficulty in obtaining stomach contents is unquestionably due to lack of knowledge just where the stomach and its contents lie in the abdomen. The man who does not know whether he must introduce 40 or 55 cm. of tube will naturally find trouble, for he may not reach even the surface of the stomach contents, or he may introduce so much tube that the end, after touching the greater curvature may turn around and go upward along the lesser border and so above the fluid level, or he may even poke the tube into the pyloric canal, or induce so much nausea that duodenal contents are regurgitated with a certain vitiation of the chemical findings. The acidities may not be the same in all parts of the stomach contents, and it is especially important not to obtain only the upper layer, which may contain much alkaline saliva and mucus. So it is necessary to know the position of the greater curvature of the stomach, to know

whether the stomach, an hour after the test breakfast, is comparatively full or empty, and to measure the length of tube necessary to reach from the incisor teeth to the middle of the greater curvature by placing the tube, just before it passage, along the cheek, neck, chest, and abdomen to the middle point of the greater curvature. Then we know with some accuracy just how much tube to insert, and then we can work quickly to the satisfaction of the patient and ourselves. Pass the tube once, if needed, and make the diagnosis. The more often a tube is passed for diagnosis, the more probable it is that there is no clear diagnosis, and the less chance there is of the trouble being primarily in the stomach.

If there is a question of failing HCl for the diagnosis of cancer, or of the return of HCl in subacidity, or its diminution in ulcer with reference to continued treatment, or if there be a question of variation in a short period, then the tube may be passed as seems fit. It would perhaps be wise for all those suffering from chronic gastric disorders to have a regular monthly internal gastric examination, especially those past forty and those suffering from chronic ulcer, so that any change in acidity or any appearance of blood or evidence of stenosis might give the first danger signals of beginning carcinoma. It is possible that the frequent application of the Abderhalden malignancy test might serve the same purpose. Otherwise to pass the tube once, to pass it safely and comfortably for the patient, to know where it is being passed, constitute the reasonable use of the stomach tube. Its repeated use argues for bad technique, bad diagnosis, or bad treatment.

Lastly as to the question whether the stomach tube is passing. An extended answer is hardly necessary after what has been already said as to the proper indications and use of the instrument. In one sense it is passing, and rightly so; its indiscriminate and unbased use, either for therapeutic or diagnostic purposes can be only decried by medical reason. But if it does real therapeutic service and can give positive or negative aid in abdominal diagnosis, it is not passing, and will not pass as long as there is regard for medical values and the welfare of the patient. The physician or the surgeon, who, in cases of obscure abdominal conditions, does not consider the possibilities of the stomach tube, opens himself to the charge of medical or surgical narrowness, or else lack of knowledge.

Where one sees cases of duodenal ulcer diagnosed as intestinal indigestion, colecystitis as gastritis, colitis as gall-stones, gumma of the stomach as dyspepsia, spastic constipation as appendicitis, appendicitis as ulcer, fetal membranes about the ascending colon as ovarian cyst, mucous colitis for imminent death from duodenal ulcer, it is fair to assume that the stomach tube is not passing in value or in use in the hands of those who recognize its possibilities for an accurate diagnosis and efficient medical or surgical treatment. It has been said that medicine is today so complex and voluminous, that no one human mind can be master of it all. The best we can do is to apply the rule of reason, whether in medicine or surgery. We can then reach the best diagnosis, institute the best treatment, with the greatest comfort and good of our patients and ourselves.

## THE ETIOLOGY AND SURGICAL TREATMENT OF GASTRIC AND DUODENAL ULCER.

By James Spencer Brown, M.D.,

Montclair, New Jersey.

Surgeon in Chief, Mountainside Hospital.

From a résumé of the recent literature on chronic ulcer of the stomach and duodenum, one would gain two impressions: first, that the etiology of the disease is in doubt; and, second, that the treatment by surgical intervention is entirely satisfactory. As a matter of fact both of these impressions are only partially true.

A special committee organized in Germany to investigate the cause of ulcer of the stomach a short time ago, reported as follows: "The nature of ulcer of the stomach has not yet been explained. Even if we have been successful in producing gastric ulcers artificially with all their characteristic signs, yet the etiology of gastric ulcer in man is practically unknown." In speaking of the experimental investigators, Schültz[1] says: "All these investigators labor under the difficulty that the ulcerations which were produced experimentally resemble the ulcers observed in man in their appearance but not in their course. They have confirmed the old experience that local disturbances in circulation play a part in the production of ulcers; but they have not been able to give an adequate explanation of their peculiar course." Aschoff,[2] referring to the mechanical conditions which are of importance in the pathogenesis of gastric ulcer, concludes that although disturbances of the circulation of all sorts are important in the development of acute ulcer, mechanical conditions *not* primary disease of the blood-vessels influence their chronic character, location, and shape. Thus the prolonged contact with gastric juice, and mechanical friction and stress at the lesser curvature, act as important factors. Sherren[3] and others have called attention to the fact that although it is found possible to produce gastric ulcer experimentally as a result of injury to the mucous membrane, injury to nerves, embolism and thrombosis, and local infection, the ulcers so produced usually heal rapidly. He quotes Bolton as showing that gastric ulcers are due to the action of the gastric juice upon devitalized gastric mucous membrane. "By injecting into guinea-pigs gastrotoxic serum prepared by injecting the gastric-cells of the guinea-pig into the rabbit, areas of necrosis and punched-out ulcers were produced. The formation of these could be prevented by neutralizing the gastric juice with 20 c.c. of a 1 per cent. solution of bicarbonate of sodium. Hyperacidity of the gastric juice alone would not produce ulcers, but any excess of hydrochloric acid increased the lesion produced by the injection of gastrotoxic serum."

Ophüls[4] believes that gastric and duodenal ulcers arise primarily from vascular lesions, and calls attention to a statement of Hauser as offering an explanation of the failure to produce chronic ulcers by experiments which otherwise confirmed the theory first suggested by Virchow that local vascular disturbances influence gastric ulcer. The statement of Hauser[5] referred to, is as follows: "In case of local disease of the gastric vessels the ulcer assumes a chronic atonic character, because the development of the blood vessels can not occur normally from pathological blood vessels. The degree of vascular disease, therefore, determines the more or less chronic character of the ulcer." W. J. Mayo[6]

several years ago called attention to the appearance of an anemic spot on the duodenum on the slightest stretching. And Ophüls points out the frequent erosion of arteries at the base of the ulcer, followed by severe arterial hemorrhage, as pointing strongly to a relation of the ulceration to local disease of the arteries. "Any one who will take the trouble to dissect the arteries of the stomach," says Ophüls, "will be astonished to find how poorly supplied with arteries are those parts of the wall of the stomach and duodenum where we usually find ulcers. This is particularly true of the extreme pyloric end of the stomach at the lesser curvature and on the posterior wall, and of the beginning of the duodenum at its convexity." Ophüls draws the following conclusions from his observations: (1) "The most common type of gastric, or duodenal ulcer, at least in material obtained by necropsy, is the arteriosclerotic ulcer in persons over 30 years of age. (2) There is a second class of gastric (or duodenal) ulcer, in the young, which is probably due to local endarteritis (thrombo-arteritis). (3) In addition to these, one occasionally observes acute embolic (or thrombotic) ulcers."

D. P. D. Wilkie (Laboratory Reports of the Royal College of Physicians, Edinburgh, Vol. XII.)' found "that in infancy the veins of the portal system are provided with competent valves, but that with age the great majority of these become incompetent. After these valves no longer serve to regulate the blood-flow through the veins in which they are situated, there is a rather frequent tendency to an 'oscillation' of the blood in the portal vessels. Under the influence of changes in the blood pressure, respiratory movements, or the distention of the stomach with food, the blood returning from the omentum may be diverted from its usual course and may traverse the gastric venous plexus, which thus comes to act as a filter for the omental blood. Wilkie concludes that one of the important functions of the omentum is to aid in the localization of peritoneal inflammation and that in the performance of this function it is apt to suffer injuries from which it does not fully recover. He was able to demonstrate that thrombosis occurs readily in the thin-walled veins of this tissue and believes that thrombi in such a mobile situation would easily become broken up. In order to test out his hypothesis he produced thrombi in the omental veins by means of a simple ligation or by searing the tissues alongside the vein with a hot platinum needle."

It must appear to everyone that all these investigators are dealing with end results and not with the primary cause of ulcer of the duodenum in man.

The most attractive theory so far advanced is that of Sir Arbuthnot Lane, namely, that ileostasis plays an important part in the etiology of the disease. His theories do not conflict with those advanced by investigators who regard the action of toxins on the blood vessels as a late cause of ulcer.

The permanent relief of symptoms by surgery is successful in from 78 to 96 per cent. of the cases, the statistics varying with different operators, and the length of time from the operation to the time of report. Our personal experience is that three years after operation, 82 per cent. of our cases are still well and without symptoms.

What are the causes of failure? It has been customary to treat ulcer of the stomach or duodenum by excision of the ulcer either alone or combined with gastrojejunostomy, using either the anterior or posterior method, depending on whether the operator regarded the beneficial result as due to an anatomic drainage or entirely a physiological operation, reducing intra stomach pressure and adding to the acid chyme duodenal contents, namely, pancreatic juice and bile. It has been the habit of some operators to shirstring the ulcer, while others have punctured the ulcer and repaired the small puncture because of the known fact that cases operated upon for ruptured duodenal ulcer generally heal and remain well.

Recently there has been an honest discussion among surgeons as to whether a pylorectomy should be added to the gastrojejunostomy in every case where the ulcer involves the pylorus and where the operation was possible, and it seems to the writer from his experience, and from what is known at this time, that the whole matter of failure in a small percentage of cases must depend upon this added detail.

There are as yet very few statistics available upon this point, but taking those of Deaver, Mayo, Moynihan and a few others, it would seem as though this procedure would add about 8 to 10 per cent. to the mortality of the operation. This would be a rather larger added risk than was justifiable if this was the only point to be gained, but it is impossible to say when the ulcer is found, whether it is simple or malignant macroscopically and without microscopic section. One does not have to proceed far in stomach surgery if he is honest until he is willing to admit his inability to differentiate many of these ulcers.

The following case is illustrative:

D. F., United States, consulted me in 1911 for pain two hours after taking food, with no loss of flesh or strength, no vomiting at any time. His stomach contents were normal, chemically and microscopically. I saw him again in consultation in September, 1913. He was vomiting all food and was then emaciated. His stomach contents showed a high percentage of free and combined acids, a few red cells, a few yeast cells, and a trace of mucus, otherwise microscopically negative, no Oppler bacilli or other forms of fermentation. Physical examination was negative for tumor. Slight resistance and pain over pyloris. It was evidently a surgical case and I operated upon him the following day. There were no enlarged glands about the pylorus which was freely movable, but was the seat of a large saddle ulcer occluding the pyloric valve. There was nothing about the history or ulcer in this case that would make one think of malignancy. I did a quick anastomosis by the posterior method concluding the operation in about 33 minutes. There was nothing about the convalescence of this patient that need be noticed, except that he did not gain flesh and strength as fast as people who have a simple ulcer of the pylorus generally do after operation. Six weeks from the time of the first operation, although the patient was taking a large amount of food, he did not gain flesh and strength. I reopened the abdomen, when to my dismay I found the case was one of inoperable carcinoma—the pylorus fixed, glandular involvement everywhere, the tumor extending along the lesser curvature. In other words the carcinoma had behaved as they always do after surgical interference which does not remove the entire disease, namely, had become intensely malignant and vastly more toxic.

This is one of several cases in which my inability to differentiate the ulcer at the time of the operation has deprived the patient of a chance of cure by a radical procedure—and I am sure that this is the experience of other operators, as I have seen a number of their cases which correspond in every detail with the case reported above.

I have formulated a plan of procedure for myself which forces me to perform a pylorectomy in every case in which the ulcer involves the pylorus.

Other causes of failure to relieve symptoms *are:* (1) Imperfect technique in making the anastomosis.

(2) Refusal of the ulcer to heal, although not malignant. (3) The formation of new ulcers of the duodenum distal to the anastomosis. The first must always remain a personal equation. The second is remedied by a pylorectomy or excision. In our own personal experience we have never met with a single ulcer of the greater or lesser curvature which did not heal after gastrojejunostomy. All our failures have been cases where the ulcer involved the pylorus. The third demonstrates pretty thoroughly that we are dealing with end results, the treatment of which has in no way relieved the cause.

## SURGICAL IONIZATION AND OTHER PHYSICAL FORCES IN THE TREATMENT OF CANCER.

By G. BETTON MASSEY, M.D.,

PHILADELPHIA.

THE modern revival of interest in the treatment of cancer has been stimulated in turn by the announcement of the earlier technique of the writer's method of destructive ionization with a heavy direct current of electricity, in 1895, followed a year later by the first efforts of the Roentgen ray treatment and later still by fulguration with high-frequency currents. Latest of all is the recent renewal of hope in the action of radium, under the stimulus of the expectation that larger dosage would yield results hitherto wanting from the application of the small quantities that have been available. Aside from some ineffectual experiments with sera and other biological products, it is notable that all these methods are essentially electrical, or forces resultant from ionic action, whether operating by the cataphoric conduction of ions in solution; by radiation due to ionic bombardment within the Crookes tube or the ionic decomposition of radium; or by the direct action of the ions produced by the high-frequency current.

An additional fact of interest is the possibility that the popularity of this whole group of methods, including the biological experiments, indicates a growing conviction that cancer is parasitic. This etiology would at least seem to be suggested by the successful cases of any one of these methods, for the most natural explanation of such results is an interstitial devitalization, or retardation of growth, of an endocellular hyperstimulating organism. That the surgical mind is tending in this direction also is evidenced by the recent elaborate precautions of some surgeons against reinfection during operations. It seems to the writer that this interpretation of our therapeutic efforts should be frankly faced, with a view to a possible increase in the parasiticidal effects that might flow from a clearer comprehension of their mode of action. It would by no means be the first time that a successful antiparasitic treatment had been employed in advance of laboratory corroboration of such an etiology.

Analysis of the action of the physical agencies mentioned above shows two methods of destruction or retardation of the life of lower organisms:

(1) The writer's method of massive diffusion of zinc ions, by which these ions are driven into union with the protoplasm and saline constituents of the diseased cells, is an immediate destructive agency for the growth as a whole, accomplished in from twenty to forty minutes by a process of electrochemistry. This is applicable in early or small growths at or near the surface because of its simplicity, bloodlessness, and small resultant scar. It is also strongly indicated in certain large and neglected growths that are on the borderline of knife operability, owing to the ease with which the destructive sterilization may be carried into cavities and to points of extension that could not be eradicated by excision without reimplantation of infected cells. It has the additional advantage of sealing the absorbent vessels at the periphery of the destroyed growth, thus placing the dead tissue practically outside the body, with no vascular connection with the body system and with no possibility, therefore, of producing a toxic effect. This sealing of lymphatics and veins also makes reimplantation of diseased cells impossible.

(2) Recent investigations of radium indicate that the effective gamma rays from this substance are probably identical with the penetrating rays of hard Roentgen tubes. These latter have been in the main a disappointment in the treatment of serious growths, though at times effective, and often a valuable palliative. It is likely that their curative value may be increased by improved apparatus, giving new possibilities to the method in otherwise intractable cases. Roentgen rays are contraindicated in early local growths that are amenable to quick destruction by simpler means. Their slow action permits metastases to form. It is also difficult to confine them to the diseased part, resulting in unnecessary risk of detrimental action on other portions of the body. The practice of repeatedly flooding large parts of the body with rays for the destruction of a small epithelioma of the skin seems indefensible, in view of the ease with which such a growth may be destroyed by ionization, or even by caustics.

Of the action of large quantities of radium we are not yet fully informed. That a profound effect is produced on some growths is evident from newspaper reports and the statements of the few possessors of a large dosage in this country and Europe. It is possible that the considerable mortality reported is due to the growth being killed *within the body*, with intact absorbents and no bar to the free introduction into the circulation of an overwhelming dose of toxins. That radium will kill small skin epitheliomas is more interesting than important when it is understood that 90 per cent. of these may be eradicated by a few minutes' employment of zinc ions in an office application.

Fulguration, which is not employed as a destructive agency but as a means of rendering a post-

operative wound a poor soil for the growth after its partial removal by a cutting operation, may be classed with radiation methods if the reports of its effectiveness stand the test of time.

The writer believes that these two general methods of arraying physical forces in cancer therapy should receive a discriminating consideration alongside the knife as methods of choice in individual cases, the selection of method being dictated by our present clinical experience of its efficiency in the particular situation and conditions of the growth. And it is the situation and extension of the growth rather than its histologic type that should determine choice, all types of cells being about equally affected by these physical forces.

All will agree that a local malignant growth that can be excised without risk of reimplantation should be promptly removed by the knife. When, on the other hand, surgical measures of any kind, including the ionic, are manifestly incapable of successfully removing a local growth, our present recourse must be to some form of radiation.

The ionic diffusion method occupies a middle ground between excision and radiation in its clinical indications, for by it a still local growth, including infected glands, may be destroyed in a situation impossible of successful excision. This is borne out by the writer's experience with a large number of otherwise inoperable cases, with the result of saving the lives of about thirty per cent. of this class of patients treated, who have remained free from the disease for periods of time varying from one to seventeen years.

The effectiveness of this method has been measurably increased of late by making the application bipolar, the soluble ionizing electrodes being inserted at the periphery and the other pole of the current placed in the center of the growth. This technique is best adapted to the quick destruction of large growths, for one may employ several thousand milliamperes without the current itself traversing and tetanizing nearby nerve structures, greatly shortening the time of operation. Profound local or general anesthesia is essential to thorough work, preferably preceded by the hyoscin-morphia combination.

The results in cases treated by the older, unipolar, method, in which a large pad of wet kaolin forms the negative pole on a distant skin surface, have been given in the writer's monograph on the subject.* During the last ten years 234 cases of cancer have been operated upon, mainly by the bipolar method, with the following results:

Of the 234 patients, presenting mostly inoperable growths, 95 patients, or 40.6 per cent. have remained free from manifest evidence of disease for periods of time varying from one year to ten years since treatment. Nine patients died during treatment—a mortality of 3.84 per cent.

The microscopical diagnosis and results in these cases may be tabulated as follows:

Of 111 epitheliomas, 77 were cured, 32 received temporary palliation, and 2 died.

Of 104 carcinomas, 32 were cured, 65 received temporary palliation, and 7 died.

Of 19 sarcomas, 7 were cured and 12 received temporary palliation.

The cases of epithelioma yielded 70 per cent. of cures, the carcinomas 30 per cent., and the small number of sarcomas 36 per cent. of cures.

## A SKIN VARNISH AND SUBSTITUTE FOR RUBBER GLOVES.

By ELLICE McDONALD, M.D.,

NEW YORK.

Rubber operating gloves are such an article of religion with modern surgeons that he who suggests their elimination is thought heretical; yet they have their obvious disadvantages. They are not easy to operate with, particularly in intestinal operations, where the slippery gut eludes the grasp. The sense of touch is decidedly altered and deadened, not only by the interposition of the rubber itself, but also by the constriction of the fingers by the elastic tissue.

These drawbacks would not be considered were gloves perfectly safe in regard to infection. They are difficult to sterilize and require fifteen minutes' boiling in water, or one hour in the steam sterilizer at 120° with 15 pounds pressure. Braun (*Beiträge zur klin. Chir.*, 1908, LXIV. 2) found that when tightly wrapped rubber gloves required one hour's steam sterilization; three-quarters of an hour did not suffice unless the gloves were loosely packed and the fingers distended by cotton. He favors placing a cotton glove inside the rubber in order that the steam may penetrate. It is probable that most surgeons are not familiar with the difficulty of sterilizing rubber gloves. With a proper amount of sterilization rubber gloves soon deteriorate in quality.

Then, again, gloves are frequently pricked by needles, and torn, liberating bacteria suspended in the perspiration of the hand—the easiest possible form by which to transmit infection. The hands always sweat, and the sweat collects with the skin bacteria at the loose finger ends. When a needle prick comes the bacteria escape into the wound. Hellendan and Fromme (*La Semaine Medicale*, Dec. 4, 1912) found that in forty-six of ninety operations the gloves of the surgeons after operation contained liquid, sometimes to the amount of several cubic centimeters. Cultures showed that this liquid contained two, three, and even ten times the number of organisms recoverable from the hand before the glove was put on, and in some cases, more than before the hand was treated. Putting on the gloves dry did not alter the result. This is a commentary upon the danger of glove punctures and the inefficiency of present methods of hand disinfection. Bad gloves, or gloves with needle pricks, are infinitely more dangerous than the bare hands, even when these are treated in the customary inefficient manner.

Gloves are used to prevent contamination from the hand to the wound, and if this may be obtained after another fashion gloves may be dispensed with.

This may be accomplished by means of a coating of the skin by a substance which is impervious, smooth and elastic, with all movements of the hands. This is no new idea, and skin varnishes have been described by many others. Weil pasted rubber sheets to the skin of the abdomen and the surrounding of the operative field was attempted by Murphy with an acetone gutta percha solution. Menge attempted disinfection with paraffin-xylol, and Schleich used wax. Others were Lesai's varnish, Kossman's chirol, Daederlein's guanidin, Wederhake's rubber skin, Dornitz and Klarpp's chirostes, Heusner's iodine-collodion, v. Herff's benzodamar, Dubar's varnish and v. Oettinen's mastisol. I have investigated all of these that I could obtain, and few have any merit save mastisol. Rub-

ber, wax or damar solutions are too soft and pervious for any practical use.

As a result of considerable experiment, I have devised a skin coating which is impervious, easily applied and sterile. It has the following approximate composition, but requires to be standardized at the factory in regard to consistency on account of the strange ways in which soluble cotton acts in solution. It is composed of a base of pyroxylin (soluble cotton of commerce) dissolved in amyl acetate and acetone, with the addition of propyl and ethyl alcohol and saponifiable ester. It contains one per cent. of a strong oil—soluble germicide. The varnish is a golden yellow liquid, having the consistency of maple syrup.

This solution has the following advantages: It is readily applied and removed; it is insoluble in all water solutions and not affected by the heat of the body; it adheres strongly to the hand and penetrates all the crevices of the skin, fixing the bacteria; it goes readily under the nails, where the most organisms reside; it cannot be scraped off the skin with a knife, the superficial layers of the skin itself coming away along with the varnish if pressure is exerted.

After the hands are sterilized, and reasonably dry, a small quantity is poured in the palm of one hand and then rubbed over all surfaces of both hands, as if it were vaseline or other grease. Care should be taken to coat every part; as soon as stickiness begins, the hands are held quiet and waved in the air for a minute or so, until the varnish dries. If the room is hot, or it is summer, a slight stickiness or "tacky" feeling may persist; but this may be immediately removed by plunging the hands into sterile water. The varnish then is smooth, firm and elastic, and may be removed only by acetone or other solvent of collodion. The best solvent for removal is equal parts of acetone and denatured alcohol, both of which may be obtained from dealers in painters' supplies. Removal is best done by a piece of absorbent cotton and a saucer of the alcohol-acetone solution. An orange stick is useful to work under the nails.

This varnish fixes the bacteria upon the skin, as I have shown repeatedly, by the following experiment: Without any preliminary disinfection or other cleansing whatever, a twenty-four hour broth culture of *Staphylococcus pyogenes aureus* was poured on the hand and allowed to dry in. The hands were then coated with the skin varnish, which was allowed to dry as above described. Cultures were then taken by vigorous scraping with a knife from the coated surface; all were uniformly sterile. To prove that this was not due to inhibition from the germicide contained in the varnish, the plates were subsequently infected, showing vigorous growth after twenty-four hours' incubation. The germicide contained in the varnish is not in a water-soluble form, so there is no danger of it or any of the constituents of the varnish passing into the wound at operation.

The ease and skill which is gained in operating with the varnish is such that once used it is never relinquished. The retention of the sense of touch and the removal of the bonds of rubber gloves will bring to surgeons the dexterity of the old-time surgeons of the pre-anesthetic days, of whom stories of half-minute amputations are still told. I have used the varnish in the place of gloves for more than a year, and it has reduced my operating time for such operations which are technically alike, as hysterectomy for fibroids, by about forty per cent. Operating becomes a pleasure and skill is easily obtained. The skin varnish is also serviceable for many other purposes, such as protecting the skin around an artificial anus or coating over a healing wound at a second operation in another situation.

I am indebted to Mr. John Reilly of New York for much practical advice and assistance in the two years of experiments.

174 West Fifty-eighth Street.

## PITUITARY PREPARATIONS IN POSTOPERATIVE CONDITIONS.

By T. W. HARVEY,

ORANGE, N. J.

SURGEON, ORANGE MEMORIAL HOSPITAL.

THE most troublesome symptom following laparotomies is undoubtedly the condition known in hospital wards as gas-pains. The convalescence even from the most trivial operations is often made unbearable by the discomforts due to delayed peristalsis; the paralysis that results from insults to the nerve supply of the abdominal organs.

These cases usually require the hypodermic injection of morphine. As a rule there is very little objection to the use of small hypodermics of morphine after operation but its use delays the starting up of peristalsis and in some patients causes vomiting.

The gas-pains, as is well known, last from two to six days depending on a variety of circumstances. If peritonitis is present then the delay in starting up of peristalsis is of much more serious import, and we are confronted with the danger of that condition of intestinal paralysis with great distention and persistent vomiting that marks the fatal termination of such cases.

During the last few months in our surgical work at the Orange Memorial Hospital we have been using hypodermic injections of pituitary extract ½ to 1 c.c., beginning either immediately or about 4 hours after operation and repeating as the nature of the case requires, rarely giving more than two doses. The immediate effect is to cause the patient to void urine. This is so certain that we have used it for that indication often when otherwise we would have had to use a catheter. The next effect is to stimulate peristalsis, and the patient is soon expelling gas and consequently there is very little pain and morphine is not required.

We have used the pituitary preparation in preference to eserine in those cases of suppurative peritonitis where operation has been followed by paresis of the intestines, and enemas and cathartics are ineffectual and vomiting is intractable. Here properly administered it will change the aspect of the whole situation and will stimulate the bowels to move and the stomach will recover its tone.

This particular effect of pituitary extract upon the muscular coat of the intestines and its application to postoperative conditions has not been dwelt upon in the literature of this medicinal agent, its efficiency in obstetric practice having overshadowed its good effects in surgery. Our records show that we have used this preparation in some thirty laparotomies and always with benefit.

Case I.—C. N., July 20, 1913. Gangrenous appendicitis, drainage. Three hours after operation morphine and atropine given by hypodermic for severe abdominal pain. The pain returning, pituitary extract was given twice in first twenty-four hours; the patient

had watery movements with gas the next morning. The drug was given once a day for two succeeding days, causing free expulsion of gas and relief of pain.

Case II.—J. N., September 1, 1913. Suppurative appendicitis; gangrenous appendix. Patient had a peritonitis following operation with vomiting and abdominal pain. This patient had two hypodermics of morphine and two of pituitary extract with relief of symptoms after the first forty-eight hours. In both of these cases peritonitis was so marked as to require the Murphy drip and the Fowler position.

Case III.—P. L., September 14, 1913. Admitted in a condition of collapse following rupture of a large appendical abscess. Active cardiac stimulation with Murphy drip and one small dose of morphine was given immediately; pituitary extract was given in twelve hours and again in twenty-four hours after operation; gas was passed from the bowels and there was great relief of abdominal pain and vomiting. Patient had a stormy convalescence, having a septic pneumonia, but his recovery from his general suppurative peritonitis was very rapid and satisfactory. This patient was about the sickest patient with peritonitis that I have ever seen recover. He was practically pulseless at the time of operation, which was a simple incision with drainage, and for twenty hours required constant stimulation. The administration of the pituitary extract and the starting up of peristalsis I am sure turned the scales toward recovery.

Case IV.—M. H., September 20, 1913. Pelvic peritonitis, colloid cyst of the broad ligament, many adhesions, drainage. Immediately after operation morphine was given, pituitrin was given at 8.45 P. M. and at 8 A. M. the next morning, all gas pains were relieved, pain returning the next morning, the pituitary extract was given again with early relief.

Case V.—P. M., September 25, 1913. Laparotomy for extensive adhesions about cecum and stump of appendix. Pituitary extract was used twice during second day after operation with relief of pain and the passage of gas.

Case VI.—C. B., October 1, 1913. Catarrhal appendicitis, cystic ovaries; two doses of morphine after operation, pituitary extract twice in first twenty-four hours with relief of abdominal pain.

Through the courtesy of Drs. Ranson and Blakely of the Hospital Staff I can report the following cases from Dr. Runyon's service:

December 1, 1913.—S. Ruptured pus tube, general peritonitis; pituitary extract in two hours and twenty-four hours after operation; severe abdominal pain relieved on second day by discharge of gas and feces. No morphine.

December 6, 1913.—B. Appendicitis and adhesions, pituitary extract and morphine once after operation; bowels moved twenty hours after operation.

November 21, 1913.—C. Appendicitis, Lane's "kink"; post-operative pain very severe, morphine four times, pituitary extract four times in first forty-eight hours, then relieved by bowel movement.

December 2, 1913.—S. Fibroid uterus, hysterectomy; pituitary extract once four hours after operation, no gas pains.

December 1, 1913.—M. Appendectomy and Gilliam's operation; pituitary extract ten hours and thirteen hours after operation, no gas pains, bowel movement thirty hours after operation.

December 13, 1913.—O. Appendectomy; pituitary extract four hours after operation, no post-operative pain.

December 16, 1913.—G. Appendectomy, gangrenous appendix; pituitary extract four hours after operation, no gas pains.

December 15, 1913.—W. Gillian's operation, pituitary extract and morphine once six hours after operation; no gas pains.

Many cases of appendectomy have unpleasant symptoms only during the first three days. The early use of pituitary extract will almost without fail render those first days comfortable. In cases of suppurative peritonitis many die because of the paralysis of the intestines as shown by the obstinate constipation and the vomiting. Here the early use of the remedy in one or two very bad cases has seemed life saving.

In our experience, using the small doses, there does not seem to be any contraindication. One patient who was much relieved of his abdominal symptoms by the pituitary extract had a troublesome tachycardia. In this case several doses had been given at very short intervals. The tachycardia was relieved in a few hours.

Any mechanical obstruction such as intussusception is a contraindication, but the pituitary preparation is useful in cases of fecal accumulation in the colon, and in fact in cases of intestinal stasis generally, as it always starts things moving.

463 Main Street.

## Medicolegal Notes.

**Medical Services to Minor—Ratification of Contract.**—Action was brought for medical services rendered to the defendant while she was a minor, living with her father and supported by him. The plaintiff relied upon a voidable contract by the defendant to pay him for the services, which she, after coming of age, ratified. There was evidence that after the rendition of the services and during the defendant's minority, she told the plaintiff that she wanted him paid therefor, and recognized the bill as a proper charge against her. Whether, in the absence of other evidence, she would have been liable upon the contract thus made, in view of her infancy and her situation in her father's family, it was unnecessary to decide, there being other evidence authorizing the inference that after coming of age she ratified her voidable contract.—Smith v. Mooney, New Hampshire Supreme Court, 85 Atl. 619.

**Malpractice—Evidence.**—In a prosecution for malpractice in treating a child's eye, the defendant testified that he made but one visit in August, 1903, when he prescribed for the eye, and that the next time he was called to see the plaintiff was in January, 1904. There was no claim that the second visit had any reference to the child's eye, and the defendant testified that that was the first time he saw that the eye was out. It was held to be prejudicial error to compel the defendant to answer questions as to whether he made any inquiry or examination of the eye between the time he prescribed for it in August and the time he discovered in January that it was out. Any such inquiries or examination could prove nothing.—Shelton v. Hacelip, Alabama Court of Appeals, 60 So. 471.

**Practising Without License—Evidence.**—In proceedings for practising without a license the evidence showed that the accused, by his public advertisements in newspapers, and to others publicly offered to practise, and professed to be able to cure practically any and all diseases, and invited all afflicted to call upon him for that purpose; but in his advertisements and in his private talk to many of his patients he would tell them specifically he made no charge. In his advertisements he stated, "Positively no charges made, but the labor is worth the hire," and repeatedly stated this to his patients. Many of those whom he treated paid him indirectly. Others paid him directly. He was known as and called "Dr." It was held that the evidence sustained a conviction for unlawfully practising without a license.—Mueller v. State, Texas Criminal Appeals, 153 S. W. 1142.

**Opinion Expert Testimony—Its Limitation.**—An expert witness may properly state what facts he knows as to the treatment of the plaintiff suing for a personal injury, and he may give his medical opinion on such facts. He may also be asked his opinion on an assumed state of facts which the testimony of other witnesses tends to establish. While he may testify as to what, in his opinion, may or may not have been the cause of a given condition, he may not give his opinion as to the ultimate fact which the jury must determine. What in fact caused an injury is for the jury. What may or may not have caused it is a matter of expert testimony.—Sever v. Minneapolis & St. L. Ry. Co., Iowa Supreme Court, 137 N. W. 937.

**Attending Physician's Opinions.**—Attending physicians, of skill and good repute, who are not experts in mental diseases, may, it is held, testify as to the mental condition of their patients, and their opinions as to such condition are admissible, when the facts upon which they base their opinions are detailed to the jury, although they may not give opinions as to the direct question to be determined.—In re Whiting, Maine Supreme Court, 85 Alt. 791.

## THE PASSING OF THE CORONER.

THERE is a bill now before the Legislature of this State which deserves the active support, not only of every physician, but of every citizen who has the advancement of the public good at heart. We refer to the bill introduced by Mr. Brennan, entitled: "An Act to amend the Greater New York charter, creating the offices of chief medical examiner, deputy chief medical examiner, and assistant medical examiners, prescribing their powers and duties, abolishing the office of coroner, and repealing certain sections of chapter four hundred and ten of the laws of 1882 in relation to coroners." The purpose of this bill, as outlined in its title, is to substitute for the present antiquated coroner system that of medical examiners, which has existed for more than thirty-five years in Massachusetts, to the great benefit of the community.

The bill creates a new officer, to be known as the Chief Medical Examiner, upon whom, assisted by a staff of assistant examiners, etc., will devolve the responsibility of investigating the causes of violent deaths occurring in New York City. This chief medical examiner, who must be a skilled pathologist and one with at least ten years' practical experience in the performing of autopsies, will be appointed by the Mayor and will hold office until he resigns or is removed for cause and after a hearing. He in turn will appoint such assistant examiners, microscopists, pathologists, chemists, clerks, etc., as may be authorized by the Board of Estimate and Apportionment. The duties of the present coroners, after January 1, 1915, will consist only in the holding of inquests in such cases as are brought before them by the district attorney and in the exercise of the powers of magistrates in connection with such cases, the coroner's jury will be abolished, and this absurd and useless survival of a bygone age will cease to exist.

This bill, which has been endorsed by many civic, legal, and medical associations and warmly praised by the medical examiner of Suffolk County (Boston) who has the advantage of a long practical experience with the working of the system in Massachusetts, was the outcome of a conference by representatives of the City Club, Citizens' Union, Short Ballot Association, New York Academy of Medicine, Trustees of Bellevue and Allied Hospitals, the Professors of Pathology in the three leading medical schools of the city, and the District Attorney's office. It is the result of an earnest effort on the part of those who have the best interests of this city at heart to do away with one of the most wasteful, useless, and potentially evil systems in our present government. A somewhat similar bill was passed by the Legislature nine years ago, but was killed by Mayor McClellan. If the present bill is passed there is little fear that it will meet the fate of its predecessor, and to ensure its passage every physician in the city is urged to write to his Senator and Assemblymen in support of the measure. It is a good bill and its passage will bring about a reform of the greatest moment.

## THE CLINICAL VALUE OF THE WASSERMANN REACTION.

IT is now nearly eight years since the original publication of Wassermann, Neisser and Bruck, in which they described their successful adaptation of the complement-fixation reaction to the diagnosis of syphilis. As with many new things, it was at first hailed as an absolutely sure method. Later, failures were reported, and the profession for a time lost faith in its worth. More careful investigation and supervision of methods has resulted in a reinstatement of the Wassermann reaction in its proper position as a diagnostic method of high value, though it has not abolished the need for careful and painstaking physical examinations. A new edition of Boas' work on the Wassermann reaction[1] furnishes a critical discussion of the technique and clinical value of the method, and, as such, is interesting at this time. The many modifications of the original technique are discussed, and it is made plain that the latter is superior to all the modifications and changes that have since been introduced. In judging then of its value in any one instance the method used and the personality of the investigator are of the greatest importance.

One of the most important questions is: Is the Wassermann ever positive in the blood of patients who are free from lues, and if so, are such results apt to make diagnosis difficult? Boas reports the results in nearly two thousand control cases, and shows that a positive reaction may occur after anesthesia, in scarlet fever, malaria, leprosy, and trypanosomiasis, and possibly in beriberi and pellagra. The interference by narcosis is interesting rather than important. Leprosy and trypanosomiasis are diseases which would not cause much confusion in this country, and are probably fairly easy of differentiation in those places where they do occur. Its occurrence in beriberi and pellagra has not yet been sufficiently confirmed to allow of intelligent discussion. The test was positive in 6 per cent. of 617 cases of scarlet fever, but only as a temporary occurrence so that in the majority of cases a repetition of the test would expose the error. Also in the majority of cases of scarlet fever the diagnosis becomes evi-

[1] *Die Wassermannsche Reaktion* mit besonderer Berücksichtigung ihrer Klinischen Verwertbarkeit. Von Dr. Harald Boas, Privatdozent an der Universität, 1. Assistenarzt am Rudolph Bergshospital für Dermatologische und Venerische Krankheiten, Assistent am statens Seruminstitut zu Kopenhagen. Zweite Auflage. Price M. 8.80. Berlin. S. Karger. 1914.

dent later in the disease. This, then, would not lessen appreciably the value of the reaction. In malaria the Wassermann seems to be positive during the febrile stage in a majority of the cases. De Haan has investigated this disease[2] and found over 38 per cent. of positive reactions in 163 patients with malarial fever. This would seem to be an important finding, for it is not always possible to find the plasmodia in the blood of malaria patients, and serious error might result from a mistake under the circumstances. Fortunately, the Wassermann quickly becomes negative in these patients after a course of quinine treatment, and the differentiation is thus made relatively easily.

Boas found also that a positive reaction in a syphilitic might become negative after the ingestion of large quantities of alcohol, during fever and during the death agony. In syphilis the reaction usually becomes positive within four weeks after the infection, and remains so unless influenced by treatment. He is inclined to regard it as one of the symptoms of syphilis, and, as such, demanding treatment. It almost always becomes weaker or disappears under treatment, and in the majority of instances is the last symptom to disappear. It is therefore a valuable guide in treating the disease, and treatment should certainly continue as long as the Wassermann is positive. Occasionally in syphilitics a negative Wassermann becomes positive after small doses of salvarsan or neosalvarsan. The use of these so-called provocative doses has increased the field of its applicability to a very large extent.

It will be seen that a positive Wassermann has a greater value than a negative one, and Boas concludes that a positive Wassermann practically means syphilis. The whole burden of diagnosis should not, however, be placed upon the laboratory. The clinician is apparently developing an increasing tendency to demand from the pathologist, not a report, but a diagnosis, and it would seem that many of the difficulties into which he has been led have been due to the fact that he places more dependence upon the laboratory report than upon his own powers of observation. Only too often these reports are swallowed whole without any attempt at digestion. It will be exceedingly unfortunate if the improvement in the methods of laboratory diagnosis develops a type of physician who will be merely an intermediary between the pathologist and the patient.

## FRACTURES OF THE ACROMION PROCESS.

THESE fractures, which heretofore have been considered rather rare, are shown by Mencke (*Annals of Surgery*, February, 1914) to be of comparatively frequent occurrence. From the records of the German Hospital of Philadelphia for the years 1905-1912 inclusive, he was able to collect reports of 89 cases of acromial fracture. These varied in severity from a sprain fracture with slight avulsion of bony tissue to those involving a large part of the process. He finds that these fractures are conveniently divided into three classes: well marked fracture of a considerable portion of the process; separation at the epiphyseal line, and sprain fracture. Of 40 cases occurring during 1911-12, 8 belonged to the first group, 1 to the second, 25 to the third, while 6 could not be traced. Those of the first type present no especial features as to diagnosis, etc., differing from fractures in general. Epiphyseal separations he considers are, so far as etiology and symptoms go, merely a subdivision of the fractures of the first class. "True sprain fractures, by tearing due to ligamentous pull, are found in three locations: (1) most often at or above the acromioclavicular junction; (2) at the insertion of the coracoacromial ligament; (3) the upper surface of the acromion, usually the location of the smallest of the sprain fractures. * * * The fourth variety of sprain fracture or at least fracture of a very small portion of the acromial tip is due very evidently to a force exerted directly either (*a*) by the pressure of the humerus from below, or (*b*) by direct violence to the acromion process." Of the 89 cases of acromion fracture, 18 had other lesions also demonstrable by the *x*-ray, and affecting the acromial end of the clavicle, the head or neck of the humerus, or, in one instance, fracture of the coracoid process and head of the radius. As Mencke says, "It will be seen at once that these injuries associated with acromial fractures, sprain fractures or otherwise, group themselves into two great classes. (1) Conditions affecting the acromioclavicular junction; (2) associated injuries indicating a violent trauma involving the upper end of the humerus and producing either a luxation of the humerus or a fracture." The history given by the patients was usually of "a fall on the shoulder," but Mencke believes, and in this he is backed up by Codman, Thomas, and Davis, that this statement is generally incorrect. In the vast majority of cases he considers that since the arm is usually thrown out from the body and the force of impact so transmitted that the shaft of the humerus acts as the long arm of a lever, the injury is usually caused by the great tuberosity of the humerus. "The force applied to the acromion may then (*a*) clip its outer end, (*b*) spring the acromioclavicular junction, or (*c*) put too much strain on the coracoacromial ligament. In any of these conditions the acromial fracture or sprain fracture results." Such a force must also produce an accompanying injury to the contiguous soft parts. The symptomatology of even the apparently insignificant sprain fractures bears out this view. "A certain proportion of these cases show immediately after the injury only the two symptoms referable directly to the acromial condition, *i.e.* localized tenderness over the acromion at the seat of injury, and pain on abduction. * * * These symptoms should cease with proper treatment at a time when bony or fibrous union has taken place. The persistence of symptoms points to the existence of a concomitant shoulder condition. * * * We must then consider the accompanying lesion as being * * * a luxation of the head of the humerus, spontaneously reduced, or an injury just short of producing luxation but with similar injury to the joint capsule."

† Über das Vorkommen der Wassermannschen Reaktion bei akuten Malariakrankheiten in den Tropen. Von Dr. J. de Haan. Archiv f. Schiffs- u. Tropen-Hygiene. 1913, xvii, 693.

Whether the theory of the production of these fractures be right or wrong, Mencke has rendered a very positive service to surgery in calling attention to the relatively frequent occurrence of slight acromial lesions. The severe fractures are usually recognized, for ordinarily there is but little difficulty in their diagnosis. The so-called sprain fracture, however, is often unrecognized and may carry in its wake, when untreated, long-continued functional disturbances which are commonly ascribed to a subdeltoid or subacromial bursitis, or to "rheumatism." The gross lesions of the acromion are readily shown by the *x*-ray, but the finer lesions, the tearing away of merely a few fragments of bone, cannot always be appreciated when interpreting the plates. One point not mentioned by Mencke but which should be emphasized, particularly in connection with cases suggestive of slight bony lesions not shown by the *x*-ray, is the diagnostic value of slight ecchymosis appearing over the acromion 24 to 48 hours after injury. This, with local tenderness and pain, especially at the acromioclavicular junction, and with painful and limited abduction of the arm, but with no demonstrable injury to the clavicle or to the head or neck of the humerus, we have found clinically almost pathognomonic of acromial sprain fracture. In every case of this kind the shoulder should be put at rest for two or, better, three weeks. A well-applied muslin Velpeau usually suffices; but when the lesion is of sufficient extent to allow downward and forward drooping of the shoulder, a modified Sayre strapping, applied as in fractures of the clavicle, plus the Velpeau has given uniformly good results.

### The Feeble-Minded in New York.

The vital need for increased provision for the feeble-minded persons in New York shown by statistics recently issued through the Rome State Custodial Asylum, which appeals also for an enlargement of its plant. The number of feeble-minded persons in the State is approximately 32,000, or one in every 300, it is stated. Of these only 4,900 are cared for in asylums, while 4,500 are scattered among the State prisons and jails, reformatories, and almshouses. It follows that about 22,600, or almost two-thirds of the whole, are at large in the community. The danger of this condition is shown in the rapid increase of the feeble-minded population. The number of feeble-minded girls and women of child-bearing age is estimated at 10,000, of whom nearly 7,000 are free throughout the State, and in this connection it is stated that a feeble-minded girl or woman is considered to be three times as dangerous to the community as a man. As regards the provision which is being made for the care of these persons, it is recalled that in 1890 on the basis of one in every three hundred, the feeble-minded population of the State was estimated at 19,992, of whom 19,220 were at large, institutional provision being made for only 770. In 1913, the feeble-minded population had increased to 32,000, and although, as stated above, 4,500 were cared for in special institutions and 4,900 were under restraint in other places, there remainded 22,600 at large in the State. These figures show the pressing need for increased care for this class of persons, and it is believed that this need can be most promptly met by increasing the facilities of the Rome State Custodial Asylum where there is ample room for the erection of additional buildings. The economy of this is apparent when it is stated that at the Rome institution 1,250 inmates are humanely cared for at a per capita cost of $2.39 a week, while at the boys' reformatories the cost is $4.66 a week, and at the girls' reformatories $5.47. The removal of this class of persons from the reformatories would relieve the latter of a great burden, make way for the class better suited for reformatory care, and effect a great saving to the State by reducing the cost of their maintenance.

## News of the Week.

**Civil Service Examination.**—The United States Civil Service Commission announces for April 8, 1914, a competitive examination, open to both men and women, for the purpose of filling a vacancy in the position of medical interne in the Government Hospital for the Insane, Washington, D. C., at $900 per annum and maintenance, and other vacancies of the same sort as they may occur. The Government Hospital for the Insane has over 3,000 patients and about 800 employees. In addition to the general medical practice offered, the opportunities in neurology and psychiatry are unsurpassed. Candidates must be twenty years of age or older, unmarried, and graduates of a reputable medical school since 1909, unless, having graduated before that date, they have been continuously engaged since graduation in work along the lines of neurology or psychiatry. Application for the examination should be made at once to the United States Civil Service Commission, Washington, D. C. As considerable difficulty has been experienced in filling vacancies in the position of medical interne in the hospital service during the past several years owing to the limited number of eligibles available, qualified persons are urged to enter this examination.

**Rise in Death Rate.**—During the week ending March 7 the deaths in New York City numbered 1,957, giving a death rate per 1,000 of 18.28. This was a considerable increase as compared with preceding weeks or with the same week of last year when the total number of deaths was 1,723 and the death rate 16.73. The most important factor in the increased mortality was the increase in the number of deaths from influenza and from chronic oragnic diseases, in the latter instance the epidemic of influenza and the severe weather conditions during the week being responsible for the termination. There was a comparatively slight increase in the number of deaths of children, and the increased mortality was largely confined to adults and old people suffering from the chronic diseases which made them unable to stand the extreme cold.

**Dr. Harry G. Watson,** formerly of New York, has removed to the Brockman Building, Los Angeles, Cal.

**Radium Ore Bill.**—The Senate Committee on Mines and Mining has agreed to report the bill conserving the supply of radium-bearing ores. This bill provides that deposits of carnotite, pitchblende, and all other ores may be explored, occupied, or purchased under the mining laws only on condition that the radium-bearing ores shall be sold exclusively to the United States. The sum of $450,000 is appropriated for building a plant and operating it for the next fiscal year.

**"Medical Judges" Bill.**—A bill recently introduced into the New York State Legislature provides that there shall be at least one medical judge in each county, three on the Court of Appeals, and three on each Appellate Division of the Supreme Court, who shall sit when any medical evidence is to be offered. Under the bill the judges would be appointed for five-year terms at $7,200 a year with an additional allowance of $2,500 for expenses. They would sit when any evidence as to sanity was to be given, and would advise the court and instruct the jury as to the correctness of statements and conclusions of medical witnesses.

**German Postgraduate Work.**—The Düsseldorfer Akademie für praktische Medizin, Dusseldorf, Germany, announces the following courses of study for physicians to be offered during the summer and autumn of this year: 1. A fourteen-day course on social medicine, treatment of injuries, and care of chronic diseases, from July 6 to 18. 2. A course in the newer methods of surgery and gynecology, consisting of lectures, demonstrations, and operative clinics, given with the assistance of the visiting physicians as well as of those of the academy, under the direction of Prof. Dr. Witzel and Prof. Dr. Pankow, during the last week of September. 3. A course in the pathology, diagnosis, and treatment of diseases of the heart and vessels, given under the direction of Prof. Dr. Hoffmann, from October 19 to 27.

**General William C. Gorgas,** who has been in South Africa investigating the health conditions in the Rand gold mines, arrived in London on his way home on Tuesday of this week. On Monday he will be the guest of honor at a dinner given by the London medical profession.

**Rush Medical College.**—In order to carry out a plan to make the Rush Medical College an integral part of the University of Chicago, with which it is at present merely affiliated, a joint committee composed of the faculties and boards of trustees of the College and the University are at present trying to raise a fund of $1,300,000. Of this it is planned to use $300,000 to provide a building for educational purposes, while the remainder will form an endowment fund through which it will be possible to raise the standard of medical teaching in the College.

**Lecture on Cancer.**—Prof. James Ewing of Cornell University Medical School, New York, will discuss the value of radium in the treatment of cancer at a public meeting arranged by the American Society for the Control of Cancer at the Woman's Cosmopolitan Club on Monday, March 23, at 3:30 o'clock.

**Gifts to Charities.**—St. Luke's Hospital of Shanghai, China, receives a bequest of about $9,000 by the will of the late Miss Fanny Whittel of this city.

By the will of the late Mrs. John W. Minturn a bequest of $15,000 is made to the Hospital for Scarlet Fever and Diphtheria Patients, which was founded by Mr. Minturn.

The Presbyterian Hospital, New York, receives a bequest of $40,000 for the endowment of free beds, by the will of the late Mrs. Minnie Hackett Trowbridge.

The sum of $5,000 each is bequeathed to the Maternity Hospital and the Howard Hospital for Incurables of Philadelphia, by the will of the late Joseph Wright of that city.

**To Abolish Coroners.**—The Assembly Committee on Cities of the New York State Legislature gave a hearing on March 11 on the bill providing for the abolition of the office of coroner in New York City. Under this bill the bulk of the work now assigned to the coroner would be taken over by a chief medical examiner appointed by the Mayor and several deputies appointed by the chief examiner. The chief and the deputies would all be physicians. The remainder of the coroner's work would be taken over by the city magistrates. There are at present eleven coroners in New York City—four in Manhattan, two each in the Bronx, Brooklyn, and Queens, and one in Richmond.

**Lectures by Dr. Bulkley.**—The Governors of the New York Skin and Cancer Hospital announce a course of clinical lectures and demonstrations in the Out-Patient Hall of the Hospital at 4:15 on Wednesday afternoons during April by Dr. Bulkley on the general subject of syphilis. The lectures will deal with primary lesions, the early and late manifestations, marital and hereditary syphilis, and the treatment of syphilis. On Thursday afternoon, April 30, Dr. William Seamon Bainbridge will lecture in the same place on "Some Practical Phases of the Cancer Problem." The course is free to members of the medical profession on the presentation of their professional cards.

**Scotch Anesthetic Society.**—At the Balmoral Hotel, Edinburgh, on February 20, a meeting which was attended by a number of anesthetists from Edinburgh, Glasgow, Aberdeen, and Dundee, was held with Dr. D. C. A. McAllum in the chair, and it was resolved that a society be formed to be known as the Scottish Society of Anesthetists, the objects of which should be "to further the study of the science and practice of anesthetics and the proper teaching thereof." The membership of the new society is limited to those practising the specialty of anesthetics. Officers were elected, as follows: *President,* Dr. McAllum, Edinburgh; *Vice-President,* Dr. Boyd; *Secretary-Treasurer,* Dr. Stuart Ross, Edinburgh; *Executive Committee,* Dr. Torrance Thomson, Edinburgh; Dr. Lamb, Glasgow; Dr. Mills, Dundee, and Dr. Johnston, Aberdeen. Two meetings will be held yearly, in April and October.

**Pennsylvania Alumni.**—The twenty-second annual dinner of the Philadelphia Alumni Society of the Medical Department of the University of Pennsylvania was held on February 21, when the following officers were elected for the ensuing year: *President,* Dr. William E. Hughes; *Vice-Presidents,* Dr. Howard A. Sutton, Dr. Samuel M. Wilson, and Dr. William A. Guilfoyle; *Honorary Vice-President,* Provost Edgar F. Smith; *Corresponding Secretary,* Dr. B. F. Stahl; *Recording Secretary,* Dr. William S. Wray; *Treasurer,* Dr. Morris B. Miller.

**Medical Society of the Missouri Valley.**—The spring meeting of the Medical Society of the Missouri Valley will be held in Lincoln, Neb., on Thursday and Friday, March 26 and 27, under the presidency of Dr. Flavel B. Tiffany of Kansas City. On Thursday evening the Lancaster County Medical Society will entertain the members of the society at dinner, after which Dr. J. Rilus Eastman of Indianapolis will deliver the annual address in Surgery, and Dr. J. M. Bell of St. Joseph the address in Medicine. Complete programs of the clinical meetings may be obtained from the secretary, Dr. Charles Wood Fassett, St. Joseph, Mo.

**Obituary Notes.**—Dr. THOMAS WILLIAM MCMANUS of New York, a graduate of the College of Physi-

cians and Surgeons, New York, in 1896, died at his home from pneumonia on March 12, aged 48 years.

Dr. JOHN E. CONLEY of Riverside, R. I., a graduate of the Baltimore Medical College in 1908, died in Naples, Italy, on February 18, aged 33 years.

Dr. WILLIAM BASS of Lowell Mass., a graduate of the Worcester Medical College in 1856, a member of the Massachusetts Medical Society and the Middlesex North District Medical Association, a former president of the latter, and a veteran of the Civil War, died at his home from pneumonia, on February 27, aged 81 years.

Dr. JOHN H. EVANS of Palestine, Texas, a graduate of the Medical Department of the Tulane University of Louisiana, New Orleans, in 1884, president of the Texas State Board of Medical Examiners, and a member of the American Medical Association, the State Medical Association of Texas, and the Anderson County Medical Society, of which he was a former president, died at his home suddenly on February 24, aged 57 years.

Dr. JOSEPH M. O'MALLEY of Philadelphia, a graduate of the Georgetown University School of Medicine, Washington, in 1893, a member of the Philadelphia Pediatric Society, the Philadelphia Neurological Society, the Medical Society of the State of Pennsylvania, and the Philadelphia County Medical Society, and for the past fifteen years chief of staff of St. Agnes' Hospital, died at the hospital from congestion of the kidneys following exposure to the severe storms of last month, on March 3, aged 49 years.

Dr. PAUL A. HARTMANS of Harrisburg, Pa., a graduate of the Jefferson Medical College, Philadelphia, in 1874, a member of the American Medical Association, the Medical Society of the State of Pennsylvania, the Dauphin County Medical Society, in which he had served as both president and secretary, and the Harrisburg Academy of Medicine, and for many years president of the school board of Harrisburg, died at his home on March 1, aged 63 years.

Dr. ALBERT PARKE GOOD of Philadelphia, a graduate of the Jefferson Medical College in 1894, and a member of the American Medical Association, the Medical Society of the State of Pennsylvania, the Philadelphia County Medical Society, and the Philadelphia Neurological Society, died at his home from heart disease on March 5, aged 45 years.

Dr. EDWARD D. GOTTSCHALK of Woodriver, Ill., a graduate of the St. Louis University School of Medicine, St. Louis, in 1906, died at St. Joseph's Hospital, Alton, from pneumonia, on February 26, aged 34 years.

Dr. HUBERT NICHOLS of Brooklyn, N. Y., a graduate of the Bellevue Hospital Medical College, New York, in 1891, died at his home on March 8, aged 49 years.

Dr. P. VINCENT MURRAY of Warren, Pa., a graduate of the Bellevue Hospital Medical College, New York, in 1881, died suddenly on March 13 while on a visit to New York.

Dr. ERWIN G. BECKWITH, retired, of Fostoria, O., died at his home from paralysis on March 5, aged 85 years.

Dr. ALBERT R. FELLOWS of Winterport, Me., died suddenly while on a visit to a patient on March 5, aged 62 years.

Dr. WELLINGTON LOCKE of Carriere, Miss., a graduate of the Medical Department of the Tulane University of Louisiana, New Orleans, in 1900, and a member of the Mississippi State Medical Association and the Pearl River County Medical Society, died suddenly from apoplexy on March 5, aged 41 years.

Dr. HENRY TUCKER HARRISON of Loch Raven, Md., a graduate of the University of Maryland School of Medicine, Baltimore, in 1874, and a member of the American Medical Association, the Medical and Chirurgical Faculty of Maryland, and the Baltimore County Medical Society, died at his home from pneumonia after a short illness on March 4, aged 69 years.

Dr. ROBERT B. GRAMMER of Fort Worth, Texas, a graduate of the Louisville Medical College, Ky., in 1883, professor of pediatrics in the Fort Worth School of Medicine, and a member of the State Medical Association of Texas and the Tarrant County Medical Society, died at his home after a short illness from pneumonia on March 1, aged 53 years.

## Obituary.

### THOMAS MORGAN ROTCH, M.D.

BOSTON, MASS.

Dr. THOMAS MORGAN ROTCH, professor of pediatrics in the Harvard Medical School, Boston, died at his home on March 9, aged 64 years. Dr. Rotch was born in Philadelphia, December 9, 1849. He was graduated from Harvard University with the degree of A.B. in 1870, and from the Medical School in 1874, and in 1893 became professor of pediatrics in that institution. He was also at the time of his death consulting physician to the Boston City Hospital, visiting physician to the Children's Hospital, and a member of the American Medical Association, the Association of American Physicians, the Massachusetts State and Suffolk District Medical Societies, the Obstetrical Society of Boston, the American Pediatric Society, and the New England Pediatric Society. His reputation as a pediatrist was international. He was the author of a text-book on Pediatrics and had also published a valuable work on "The Roentgen Ray in Pediatrics."

## Correspondence.

### OUR LONDON LETTER.

(From Our Regular Correspondent.)

OPERATIVE TREATMENT OF FRACTURES—COAL DUST DISEASES—MOSQUITO-BORNE DISEASES—ORAL SEPSIS—TROPICAL MEDICINE EXPEDITION TO EAST—OBITUARY.

LONDON, February 27, 1914.

THE discovery of *x*-rays has placed at the disposal of surgeons a knowledge of the condition of fractures which proves a valuable guide to treatment such as those in practice only a few years could not have anticipated. Compound fractures under the antiseptic system had been assimilated to simple fractures and it followed that operations which had been regularly practised on the patella should be extended to other bones. Mr. Hey Groves devoted his Hunterian lecture to a consideration of the principles involved in such operations and their clinical application. The "wait and see" policy of tying a limb to a stick and trusting to luck he said must be replaced by an accurate method which only leaves the limb to nature if and when the bones are in good position. Another necessity is to employ a

method which is mechanically efficient not only to bring the bones together but to hold them there firmly, while early movement is carried out and until solid union has occurred. The ideals he set before himself in operative treatment were: (1) Not to operate in a case which would probably give as good result by conservative treatment. (2) To employ a method which would ensure perfect anatomical restoration of form. (3) To secure such efficiency of mechanical fixation that the bone would be stronger than before fracture. (4) To do this by a plan that would last an indefinite time and not depend on the frictional grip of nails and screws on the bone. (5) To restore the limb to a state in which it can be freely moved as soon as the skin wound has healed, *i.e.* in seven to fourteen days and used for full natural function in three weeks to three months according to the bone involved.

The Milroy Lectures at the Royal College of Physicians have just been given. Dr. Shufflebotham was the lecturer this year and took as subject the "Hygienic Aspect of the Coal-Mining Industry." In the first two lectures he discussed explosions and the poisonous gases liberated in mines to prepare for which he visited Senghenydd after the disaster. Yesterday he dealt with the effect of mine dust on the health of the workers and of the temperature and humidity of the air. He pointed out that miners' phthisis or fibrosis of the lungs had almost disappeared since the Coal Mines Regulation act which had also diminished to a large extent the number of accidents. Fibroid lung such as potters suffered from was rare among coal miners and anthracosis did not seem to entail disablement. From this he concluded that coal dust was not an irritant of the lung. But he suggested that if shale dust or flue dust were mixed with coal dust with a view of preventing explosions, their silicious character might endanger the miners' lungs. He suggested also that spraying mines to render coal dust less explosive, by adding humidity to the high temperature and darkness might be deleterious to health and favor the development of ankylostomiasis, at present practically unknown in British mines.

On Monday Sir Ronald Ross, K. C. B., F. R. S., delivered a research lecture, the first of a series, at the Institute of Hygiene on the "Prevention of Mosquito-Borne Diseases." He began with a brief historical sketch of the researches which had shown these diseases to be carried by mosquitos, illustrating his statements by lantern slides and cinematograph films. Among the reasons which had contributed to free England from malaria improved drainage had led to diminution in the number of mosquitos; at the same time the parasites in man had been largely destroyed by quinine and the withdrawal of the window tax had made glass windows possible for all. There were other factors which, if they could only be eliminated, malaria would be prevented. Sir Ronald Ross lamented that we had not yet discovered the parasite of yellow fever, but he did not despair; it only wanted a well-equipped researcher to sit down and search for it in the bodies of mosquitos for about five years. Referring to municipal hygiene Sir Ronald said it might be a mistake to give self-government too early to a town, as the people generally knew very little, if anything, about hygiene, the consequence being that their town was likely to be neglected. In taking preventive measures it had to be remembered that the epidemiology of such a disease as malaria was quite different from that of yellow fever, owing to the differences in the breeding habits of the mosquitos concerned. Malaria was a rural disease and endemic; yellow fever was a town disease and epidemic. So again filariasis was endemic; dengue epidemic. The lecturer showed diagrams illustrating the way in which the incidence of yellow fever and malaria had been diminished in various parts of the world and advocated a combination of methods for dealing with the problems involved. Thus he said mosquito nets should be systematically used, the insects should also be killed as far as possible, and quinine must be taken in a proper way. Better results would be obtained by the simultaneous use of these measures than by concentrating efforts on any one of them.

A discussion on oral sepsis in its medical and surgical aspects has been held at the Harveian Society and interested a much wider circle. Dr. Wm. Hunter opened by remarking on the importance of its association with wounds in the mouth, the anatomical disposition of the teeth rendering the proximity of sepsis especially serious. So tonsillitis and chronic inflammation in the nasopharynx aggravate the danger of oral sepsis which often extends to the stomach and the septic gastritis thus set up may give rise to septic anemia. He regarded pernicious anemia as a distinct disease, but if complicated by a like disorder of septic origin treatment directed to the latter had led to greatly improved prognosis. He did not approve the wholesale extraction of teeth sometimes performed but looked for the extension of the antiseptic system to medicine as fully as it had been applied to surgery.

Mr. W. H. Dolamore as a dental surgeon did not advocate wholesale extraction except in very rare cases involving severe systematic complications. Dr. Buttar would like wholesale extractors and vaccinists to show the proportion of cases that could be properly described as cures and how far it could justify the disappointment and distress occasioned by an edentulous lower jaw in those patients who obtained no benefit. Of 10 patients of his own treated by different specialists only one professed to have been relieved. Dr. G. Coats thought it doubtful whether chronic iridocyclitis was due as supposed by some to oral sepsis. Post-operative inflammation might be and so septic teeth should be removed before intraorbital operations. Dr. Fitzwilliams agreed with Dr. Hunter that tuberculosis was likely to become engrafted on inflamed glands due to oral sepsis.

The expedition to the East of the London School of Tropical Medicine left last Friday in charge of Dr. R. T. Leiper. It is supported by the colonial office and is to investigate the mode of spread of trematode diseases, especially bilharziasis; the relation of infections in domesticated animals to those of man and the extent to which they may act as natural reservoirs. Considering the importance of the investigations the Admiralty have appointed Surgeon E. L. Atkinson, R. N., to accompany Dr. Leiper who will also have the assistance of Mr. Cherry Garrard, assistant zoologist of the Scott Antarctic Expedition. China will be the first port investigated, the Blue River Valley and then Hong Kong. On the return probably the expedition will visit the Malay States and Ceylon. The U. S. Rubber Company has offered facilities for the study of medical problems in Sumatra plantations.

Dr. Theodore Maxwell, author of "Terminologia

Medica Polyglotta: a Concise International Dictionary of Medical Terms" has died at the age of 66.

Dr. Wm. Bryce of Edinburgh died there on the 21st inst., at the great age of 93.

Dr. R. M. Bowman of Ripon has also died at the age of 92.

## THE ADHESION-PRODUCING BACILLUS.

To the Editor of the Medical Record:

Sir:—Permit me to state for publication the correction of the term *B. adhæsioformis* to *B. adhæsioformans*, and to say that there is no doubt that Dr. Scott is correct in his suggestion. I hope that this pleasant controversy concerning the name will help to stimulate further studies on this bacterium, regarding which I feel that much more work than I have performed would be welcome.

Anthony Bassler, M.D.

New York.

## Progress of Medical Science.

4. Laboratory Physiology in College and in Medical School. A. D. Bush.
5. The Treatment of Uterine Carcinoma with Cancerous Ascitic Fluid. R. M. Green and F. C. W. Konrad.

**2. Relationship between Epilepsy and Migraine.**—G. A. Waterman points out that epilepsy resembles migraine in many of its aspects. Both occur with great frequency as a direct inheritance from the family of either parent. Both recur with more or less periodicity in the individual. On the other hand the picture is that of an explosion of sensory energy. Each may be preceded by an aura referable to a disturbance in a definite cortical area. Although the aura of migraine presents the visual type in the form of scotoma and hemianopsia, while epilepsy commonly exhibits the pneumogastric aura, or the sensory or motor disturbance of the arm, face, or leg; nevertheless, one may on the other hand have the migraine attack ushered in by paresthesia of the arm, lip, and tongue (with or without aphasia), while epilepsy may be preceded by visual disturbance, as dimness of vision or scotoma. Not only may the same sort of an aura introduce an attack of epilepsy or migraine in different individuals, but in both diseases the warning may make its appearance independently without being followed by an attack. Just as in epilepsy the numbness of the hand or twitching of the fingers may come daily or several times a day over varying periods of time, only to be followed by the convulsive seizure at intervals of weeks, in the same way in a subject suffering from migraine attacks every few weeks preceded by scintillating scotoma, the author has seen the appearance of daily attacks of the scotoma alone, over periods of weeks, each attack lasting from twenty to forty minutes. The occurrence of psychic symptoms associated with the attack of migraine or epilepsy has been described by various authors; and indeed the attack in either disease may be replaced by a psychic equivalent. Another common symptom frequently met with both in epilepsy and migraine is somnolence. The features indicative of a relationship between epilepsy and migraine may be classed under the following heads: (1) The interchange of one disease for the other in different generations of the same family. (2) The appearance of migraine in early life, giving place to epilepsy later, with a resulting disappearance of the migraine or diminution of the intensity of the migraine attacks. In these cases the epileptic seizures may be ushered in by the same aura which gave warning of the earlier attacks of migraine. (3) The development of migraine attacks in patients previously suffering from epilepsy, and in whom the epilepsy has been cured by bromide treatment. (4) The appearance of symptoms of epilepsy in migraine attacks of certain individuals.

**3. Radiographic Study of the Mastoid.**—O. A. Lothrop notes that the use of the *x*-ray plate for aid in diagnosis of mastoid conditions is recent and promises to be of great value, especially in differential diagnosis between an acute mastoiditis and an acute exacerbation of a chronic sclerosed mastoid. As a rule the mastoid shows a more minute change in pathology than is shown in that of the accessory nasal sinuses. The reverse is true perhaps of transillumination. For detecting changes in the antrum of Highmore, for example, the transilluminator is more accurate than the *x*-ray, but in the mastoid the *x*-ray will differentiate between a congested though cellular mastoid, one whose cells are broken down and one that is sclerosed, while the transillumination of the mastoid simply shows some pathological condition obstructing to different degrees the rays of light. The author quotes the following statistics representing the results of his study: The total number of mastoid pictures tabulated were 460. Many others were discarded either because the plates were poor or because of insufficient data. The number of pathological mastoids were about evenly divided between the right and left sides. There were many more sclerosed mastoids on the right side than on the left but the number of acute mastoids on the left side equalized the division. Although one side may prevail over the other for a given period, the average is about the same for each side. In cases where the clinical diagnosis of chronic suppurative ear was made, 94 per cent. showed total sclerosis of the mastoid and 6 per cent. semi-sclerosis. In some cases where a diagnosis of effectus ear was made, 56 per cent. were totally sclerosed, 27 per cent. semi-sclerosed, and 17 per cent. were cellular or normal. In cases where no diagnosis of a past or present suppurative process was made, 92 per cent. had normal mastoids and 8 per cent. were sclerosed or semi-sclerosed. Ten per cent. of the cases diagnosed as acute suppurative otitis media showed sclerosed or semi-sclerosed mastoids. These represent the cases of acute processes superimposed on an effectus ear, or the acute exacerbation of a chronic ear. These latter are often difficult to differentiate clinically. The conditions found at operation were compared with the clinical and *x*-ray diagnoses in seventy-five cases.

**5. The Treatment of Uterine Carcinoma with Cancerous Ascitic Fluid.**—R. M. Green and F. C. W. Konrad have had the opportunity of observing several cases of inoperable uterine carcinoma in the gynecological wards of the Boston City Hospital. In view of the occasional relief from pain and the temporary retardation of growth which Risley had observed in cases of this type, it seemed worth while to make further trial of the method of treatment with cancerous ascitic fluid. An abundance of such fluid was obtained from one of the cases in the authors' series, and with this there were made autogenous inoculations in her case, and heterogenous inoculations in five other patients. The treatment was continued in some instances over a period of four months. As the result of their experience the authors reach the following conclusions:

The cases treated all showed a slight and irregular elevation of temperature, which, however, bore no apparent relation in its oscillations to the injections of cancerous ascitic fluid, but seemed rather to be due to septic absorption from the ulcerating surface of the cancer. The results obtained correspond with those obtained at the Massachusetts General Hospital. Cases 1, 4, and 5 gave no apparent reactions. Cases 2 and 6, according to their own statement, were relieved of pain and improved in general physical condition; the third case showed an apparent temporary relief of pain, and the tumor was apparently caused to slough, as evidenced by the tissue passed by the vagina. Four of the cases died of the disease and apparently without retardation. Two other cases were discharged and lost to observation. That the injections of serum do have a beneficial effect can hardly be doubted, but whether this effect is due simply to a serum isotonic with the blood and acting as a stimulant or whether the reaction is specific, remains still to be proven. Patients with extensive cancer are usually cachectic and ill nourished, and therefore it is easy to conceive that the injection of a highly nutritive fluid, saline and isotonic with the blood, would have a stimulating effect and aid in the improvement of the general condition, and thus probably also in the resistance to the inroads of the cancer. The reaction, however, is slight, very temporary, and shows slight or no specificity.

8. A Special Burette for Use in the Rideal-Walker Test. H. W. Mahr.

**2. Primary Lingual Tuberculosis.**—W. B. Trimble reports two cases of this condition and states that tuberculous ulcers of the tongue have the following diagnostic points: They usually affect the free border near the tip; the dorsum is generally free; they are, as a rule, superficial; the base is generally a dirty yellow, dotted here and there with minute whitish specks, which probably represent small areas of caseation necrosis; the ulcer may be oval or gyrate, but the borders are generally sharply defined against the healthy tissue, sloping, and not undetermined; the lesions are not indurated and the neighboring glands are very slightly affected. The author reaches the following conclusions: (1) The diagnosis is extremely difficult. (2) It is almost impossible to demonstrate the bacilli in the ulcer. (3) Although lues and cancer furnish the majority of ulcerations of the tongue and mouth, they are by no means the only cause. (4) In any case of tongue ulceration, tuberculosis must be reckoned with as a factor. (5 The histopathological examination alone is practically useless as a means of diagnosis between syphilis and tuberculosis, but it is of great aid in excluding cancer. The majority of tuberculous ulcers of the tongue are, in all likelihood, secondary; it is easy to prove that an ulcer is secondary, but to prove that it is primary is quite another matter.

**4. Low Blood-Pressure.**—E. E. Cornwall concludes that a low systolic pressure, provided the diastolic pressure is correspondingly low, does not necessarily mean poor circulation, although it does imply a diminished reserve power of the circulation. A low systolic pressure with a comparatively high diastolic pressure and a consequently small pulse pressure usually means myocardial weakness, with chronic nephritis, arteriosclerosis, or arterial spasm, and may be bad prognostically. A low diastolic pressure with a comparatively high systolic pressure and consequently an excessively large pulse pressure, may mean several things, e.g., a purely functional condition, a compensated aortic regurgitation, myocardial degeneration without arteriosclerosis or nephritis, toxemic irritability of the myocardium, or vasomotor dilatation from any cause. The diastolic pressure seems to be more stable than the systolic, and to show, less often than the systolic, marked variations from its normal without definite pathological cause; and the systolic pressure seems to accommodate itself to the diastolic more easily than the diastolic to the systolic. The diastolic pressure indicates the peripheral resistance, which in many cases is determined by permanent pathological conditions. Movements of the diastolic pressure beyond the normal health range cause the pulse pressure to take on an overload if an adequate circulation is kept up. Vasodilator drugs may improve the circulation by increasing the pulse pressure. Cardiac depressant drugs may lower the diastolic pressure by diminishing the systolic force and calling for a pulse pressure overload. Toxemias, both acute and chronic, can produce low blood pressure by dilating the blood vessels and by weakening the myocardium, but the greater part of their effect in the larger number of cases is probably produced by vascular dilatation, either through the vasomotor centre or locally. Chronic tobacco poisoning is a very common cause of persistent low blood pressure. It is possible for a patient to live for several hours with a systolic pressure below 60, and for several days with a systolic pressure below 70, and to walk around without particular symptoms of circulatory distress with a systolic pressure of 90, provided the pulse pressure is sufficiently large. The pulse pressure in health usually ranges between 30 and 45 and pulse pressures as small as 20 or as large as 60, if persistent, may be considered pathological. A systolic pressure of 100 or lower in an adult usually calls for treatment. Shortly before death partial asphyxiation may cause a sudden, transient rise in the blood pressure. A fall in the systolic pressure in response to an exercise test, immediately, or after a short preliminary rise and a delay in its return to the normal, while lacking positive significance, suggests the existence of myocardial weakness, as does also a failure of the pulse pressure to show a substantial increase in size in response to such a test. The neurotic factor in the patient and the personal factor in the observer may require a considerable allowance to be made for them in the interpretation of blood pressure findings; and the clinician must constantly guard against being misled by blood pressure findings, and especially against ascribing too much importance to them when not supported by other evidences of disease.

**2. Short-Circuiting the Colon.**—J. R. Eastman states that anastomosis of the caput coli at its lowest level with the rectum as a means of short-circuiting the large bowel presents all the advantages and eliminates many of the evils of the operative procedures now in use. Ileosigmoidostomy does not always drain the cecum, and while anastomosis of the terminal ileum with the rectum is somewhat more efficient, the pus formation at the blind end of the ileum, described by Werelius, may defeat the object of the operation and reversed peristalsis favor retention of fermenting food and bacteria. If the caput coli is anastomosed freely to the rectum at the lowest point possible without traction, the emptying of the cecum is favored at this point, also where direct drainage is most needed. The Murphy button may be used and is here quite safe, as it will be readily discharged here. To insure anastomosis of the most dependent part of the caput coli, the appendix should be removed if it is necessary to secure perfect drainage.

**4. Mental Disease.**—F. X. Dercum divides the causes of mental disease primarily into two groups, the intrinsic, embraced in the great factor of neuropathy, and the extrinsic causes, the infections, intoxications, visceral diseases, metabolic disorders, trauma, etc. By neuropathy he understands a fundamentally defective or aberrant nervous organization shown by peculiarities of mental development and more or less by physical abnormalities in many cases. It is not surprising that individuals with these defects should break down under the ordinary stress of living, and that such breakdowns occur early in life, giving rise to insanities of the juvenile period and puberty, and also later causing the paranoid affections of the adult. The relations of neuropathy to heredity are noticed. The hereditary factors are present in a very large proportion of the insane, especially in manic depressive insanity, dementia praecox and paranoia. This heredity is of two kinds: in one of which a specific neuropathy and in the other a more general one is transmitted, but both of these may be combined in some cases. Where the extrinsic causes come into play, the neuropathic factors in heredity are also often active. Infections, trauma, etc., are only causes of mental breakdown where the resistance is weak. The psychic causes, of which much was made by the older authors, have latterly been considered of less importance. At the most they act as an incidental support or framework on which the delusional or obsessional feeling can secure a hold or obtain concrete expression. From this point of view the author passes to the consideration of the Freudian psychology and methods of psychanalysis, which he subjects to a severe criticism. They recall the writings of Janet, to whom he thinks Freud and his followers have given too little credit. He charges them with formulating differences based on doubtful inferences and questionable hypotheses, and says that this is very evident in the Freudian explanation of dreams. According to Freud's method, the psychanalyst can find most anything that he is looking for, and there can be do doubt but that he always finds it. It is a matter of proper inquiry whether or not psychanalysis is harmful, and the author refers to Hoche's inquiry on the subject as indicating that it may be so. The psychology of insanity is one thing and psychanalysis is another, and Freud and his followers are classed by the author with the Christian scientists as a sort of an outcome of the mystic tendencies of modern times.

**6. Duodenal Rupture.**—A. B. Kanavel reports two cases of traumatic extraperitoneal rupture of the duodenum which have convinced him that a toxemia, other than bacterial, is a factor in the mortality. The ordinary type of death from peritonitis was lacking, and postmortems showed no general peritonitis such as might have been expected. The diagnosis of such cases is largely based on the excessive local tenderness and pain with nausea and vomiting shortly after the injury. The treatment must be operative. The mortality is much higher than rupture of any other part of the intestine.

**7. Ultraviolet Light as a Germicidal Agent.**—F. H. Verhoeff has shown that light cannot under any conditions destroy bacteria within the cornea, even when the latter is perfectly transparent, without at the same time severely injuring the corneal tissue. Destruction of bacteria within the transparent cornea was obtained only when a light intensity and exposure were employed sufficient to cause complete destruction of the corneal corpuscles and intense injury to the corneal lamellae. Moreover, it does not seem possible that ultraviolet light could in practice be successfully used to destroy bacteria within a corneal abscess or ulcer, that is, when the cornea was no longer clear, even with the sacrifice of corneal tissue as in the case of the actual cautery. For either the exposures would have to be impractically prolonged, or such extreme intensity of light would be required that the heating effect would exceed that of the pure ultraviolet action. It is doubtful also if ultraviolet light of such intensity could be made available for therapeutic purposes. It must be concluded, therefore, that so far as direct destruction of bacteria within any of the tissues of the body is concerned, ultraviolet light possesses no therapeutic value.

**8. A Method for Determining the Amount of Blood Passing During Transfusion.**—E. Libman and R. Ottenberg find that it is as necessary to control the amount of blood transferred during a direct transfusion as it is to control the dosage in any other therapeutic procedure. A simple arithmetical formula is given by which it is possible to calculate how much rise in the percentage of hemoglobin will be obtained by transfusion of a given volume of blood. The formula is: (Patient's blood weight × patient's hemoglobin per cent.) + (weight of blood transfused × donor's hemoglobin per cent.), divided by the patient's blood weight + weight transfused (in pounds); the quotient equals the hemoglobin per cent. reached. The patient's blood weight is estimated as one-nineteenth of the body weight. The amount to be transfused may be decided arbitrarily, with regard to the patient's need, or with regard to the donor's ability to give up blood. It is always safe to take one-fourth of the donor's blood; it is often safe to take as much as one-third of the donor's blood volume, provided the transfusion is not done too rapidly. Though the danger of overloading the circulatory system of the patient is not as great as has been thought, yet probably it is not wise to add more than one-fourth, or at most one-third, as much blood as a person of the patient's weight normally has. This needs to be taken into account only in children

or very small adults, transfused from larger donors, because in most cases a single donor will collapse before he can give enough blood to embarrass the circulation of a full-grown adult patient. If more than one donor is used this part of the calculation becomes of great importance. By means of exact weighings of either donor or patient or both, before and after transfusion, in a series of eleven cases, the authors have shown that the formula which they give corresponds quite closely to the actual amount of blood transfused. By using this calculation as a guide and determining before each transfusion the point to which the hemoglobin ought to be raised, it is possible to avoid untoward symptoms in either patient or donor. The authors have demonstrated this in a large number of transfusions. The method is of value, not only for determining the amount of blood being transferred during direct (vessels to vessel) transfusions, but also for determining beforehand how much blood ought to be transferred during indirect transfusions (whether by syringe or some other method).

**1. Operative Treatment of Fractures.**—E. W. Hey Groves emphasizes the need of the more frequent employment of operative treatment in certain groups of fracture, and also the necessity of improving our operative methods. Progress in the treatment of fractures can take place only when all methods are mastered and applied with discrimination to suitable cases. There are two things necessary for a general improvement of results. The first is that anatomically accurate reposition of the fragments, as demonstrated by the *x*-rays, should be the standard by which the treatment of each case must be judged. The *laissez-faire*, or "wait-and-see" policy of tying a limb to a stick and trusting to luck must be replaced by an accurate method of treatment, which only leaves the limb to nature if and when the bones are in good position. The second is that when one does operate one must employ a method which is mechanically efficient not only in bringing the bones together but in holding them firmly, while early movement is carried out and until solid union has occurred. The ideals which the author sets before himself in the operative treatment of fractures are: (1) Not to operate upon any case which would probably give as good a result by conservative treatment. (2) To employ a method which will ensure perfect anatomical restoration of form. (3) To secure such efficiency of mechanical fixation that at the conclusion of the operation the bone is stronger than before the fracture. (4) To do this by a method of fixation which will last for an indefinite time, and does not depend upon the frictional grip of nails and screws upon the bone. (5) To restore the limb to a condition in which it can be freely moved as soon as the skin wound has healed, *i.e.* in seven to fourteen days, and used for its full natural function in a period of three weeks to three months to the bone involved.

**4. Methods of Increasing the Accuracy of the Wassermann Reaction.**—F. H. Thiele and D. Embleton conclude that it is possible to have an extremely powerful antigen which will keep its power unaltered for months. It is possible to have an antigen which is not anticomplementary, so that summation and adjuvant phenomena cannot play a part in the reaction. The use of cholesterin and other anticomplementary substances in antigens for the Wassermann reaction not only is unnecessary but introduces a very serious source of error. The author's method of increasing the delicacy of the reaction is: (1) To diminish the amount of complement used to 1½ times only, that which will cause complete hemolysis of the system adopted. (2) To use large amounts, half a cubic centimeter or more, of inactivated syphilitic serum. (3) To use 50 to 100 units of the antigen. By this method purely anticomplementary phenomena do not play a part. Anticomplementary effects being rendered obvious in the control, true complement fixation, even when minimal, can be readily demonstrated. In this way cases which would otherwise give a slight reaction, so slight as to be doubtful on the ordinary reaction, give a full fixation; cases which otherwise give a negative can be made to give a full reaction, thus bringing in a large number of latent cases; and no fallacious results with other diseases have been obtained.

**7. Infantilism.**—Hastings Gilford points out that the difference between infantilism and dwarfism is that whereas in dwarfism there is a serious delay or arrest of growth, in infantilism there is a similar imperfection of development. The one is purely quantitative, the other qualitative. Dwarfism is, therefore, usually one of the symptoms of general infantilism, but not invariably; for just as a child of twelve may be of adult stature, so also, though but seldom, does one meet with an infantilate who is not a dwarf. The author regards infantilism as a conspicuous delay or arrest of development. The lesser degrees of defective development do not constitute infantilism, seeing that they are not such a departure from the normal as to attract attention or to throw the individual or the part affected out of harmony with the surroundings. But the condition connoted by the word "infantilism" as by the word "dwarfism" is necessarily abnormal or pathological. If consideration is confined to infantilism to the human being one may recognize two kinds or classes. In the one the man is affected phylogenetically, constituting racial, ethnic, or evolutionary infantilism; in the other he is affected ontogenetically, constituting individual or developmental infantilism. In evolutionary or phylogenetic infantilism the man as an individuel is normal. He can be regarded as abnormal only when considered as the constituent of a people or race as compared with other races of mankind. For example, the Japanese, some Chinese, and the Siamese in Asia and the Bantus in Africa show evidences of being racially imperfect when compared with Caucasians. In developmental or ontogenetic infantilism just as each of the structural units of the body is liable to degenerate prematurely so also may it continue immature, and it must sometimes happen that this immaturity is of extreme degree, constituting infantilism. Infantilism of cells is indicated by the fact that in all parts of the body single cells or groups of cells are liable to stagnate or even to be arrested in their development. It has been

shown that this is particularly likely to happen in those areas in which one kind of tissue terminates abruptly in another kind of tissue or where tracts of some fetal structure have differentiated into more than one organ at a comparatively late period of development. One may speak in a similar manner of organs which have never accomplished their destiny. Symptomatic infantilism may therefore be either toxic, or correlative, or possibly deprivational. The poisons capable of setting up infantilism are many, the most important being the products of fungi or protozoa living within the body. Chief among these are the toxins of syphilis, tubercle, malaria, enteric fever, pellagra, scarlet fever, measles, and leprosy, and of those organisms responsible for the chronic diarrheal diseases of infancy. In the production of infantilism one sometimes meets with cases which cannot be accounted for by toxic influences, which are apparently not due to the withholding of food or of food stimuli, but seem to be due solely or partly to the influence of correlation. In some cases this influence seems to proceed from the derangement or incapacity of an endocrine organ. In other cases it is difficult to account for the infantilism on this score. The morbid condition apparently arises as the result of correlations of the more primitive type in which the hormones are not concerned. Correlative infantiliism may, therefore, be of two kinds: (a) endocrinous, and (b) simple correlative. As regards endocrinous infantilism it is pointed out that there is only one form of infantilism which has so far satisfactorily been proved to be due to the absence or defect of an internal secretion, and this is thyroid infantilism. In this case three requirements are fulfilled. (1) Local examination of the gland shows that it is inadequate. (2) The administration of the gland or of its extract to a normal person produces symptoms opposed to those which characterize the infantilism. (3) The gland or its extract given to the infantilate counteracts the symptoms characteristic of the infantilism.

**6. Epidemic Cervical Adenitis with Cardiac Complications.**—S. T. Pruen during the autumn and early winter of 1912 saw several cases of tonsillitis, accompanied by unusually tender cervical glands. Convalescence was very slow, and the author accounted for the unusual severity of these cases by calling them influenzal. The striking feature of this disease is the unusually numerous large and tender glands. But though these are the features that at once arrest the observer's attention, yet the importance of condition lies in the insidious onset of cardiac lesions, which are in most cases slight; the dilatation, under rest, is temporary, but a murmur may persist. So devoid of premonitory symptoms is this complication, and so very widespread the disease, that the author believes that there must be at the present time a large number of unsuspected cases with cardiac lesions. One may be dealing with a "silent endocarditis," not as a clinical curiosity, but as a prevalent disease. The author is not prepared to determine the nosology of this epidemic disorder. It is neither mumps, rheumatism, nor septic tonsillitis; nor, as the author was at first disposed to call it, for want of a better term, influenza; nor is it glandular fever, from which it differs by the absence of nephritis except in a few instances, and of enlargement of the spleen, liver, mesenteric, inguinal, and axillary glands, and by the presence in almost all cases of tonsillitis and pharyngitis, and in many cases of mild carditis or endocarditis. Moreover, adults are more frequently attacked than adolescents, and adolescents than children. The author is disposed to regard the condition which he describes as a new or hitherto unrecognized infectious disorder, and that it is caused by a streptococcus, probably a new variety.

*February* 23, 1914.

**Treatment of Cirrhosis of the Liver with Keratin.**—Zypkin of Moscow gives a brief history of the use of keratin in medicine. In 1905 Danilowsky discovered that this substance was able to bind gelatine in the body (gluten of the Germans), the substance furnishing the chief constituent of the connective tissue. He first tested it in hepatic cirrhosis, and in 1905 made the first test in an advanced case of the cardiac type of the affection. Patient had been depending upon caffein and calomel and was becoming much worse. The keratin treatment was now continued for over a year, and the organ, at first enormously enlarged, became of normal size. Thus encouraged the author tried the remedy on a case of Laennec's cirrhosis. The primary dosage was small—five half gram tablets daily—because of the accompanying gastroenteric congestion. Bismuth was used as a corrigent, and the dose of keratin slowly increased. Caffein was also used steadily, along with the *x*-rays over the liver. After five months of this treatment during which three paracenteses were necessary no more ascites formed and all edema disappeared, with simultaneous diuresis. The size of the liver and spleen remained unchanged; in other words, the disease was arrested in its course, but no actual involution had occurred. In a second case the results were even more striking. He improved more rapidly and toward the last his treatment was ambulatory. The keratin was well tolerated by the intestine. As in the first case, the change wrought in the vessels of the liver had not become so marked as to affect the volume of the liver. In the third case there was not only an alcoholic but a syphilitic history—nevertheless there was the usual degree of improvement: ascites, edema, enlarged abdominal veins all diminished greatly—in fact, became quite normal. There can, therefore, be no doubt that keratin is an antisclerotic remedy of much greater value than iodides. Of great weight is the fact that during the months of use no ill effects attributable to the drug were noted.

**Relapsing Umbilical Colic in Elder Children.**—Two articles are devoted to this subject, both in partial reference to a recent paper by Küttner. One is by Moro, a pioneer in this subject, who considers in this paper older children than those mentioned by Küttner, who insisted that this colic may be evidence of appendicitis. Moro contends that the beforementioned colic was psychogenic in origin, and therefore amenable to psychotherapy. This naturally applies only to children past a certain age, and perhaps will be found to belong under the head of "Pals vascular crises." It may be likened also to migraine and periodic vomiting. Friedjung contributes the second

paper, which also opposes Küttner's appendicitis theory. A number of autopsies on these children have shown the appendix normal. Of course Küttner's claim that appendicostomy cures this colic is not contested. An occasional coincidence is of course possible and has occurred. Friedjung is among those who believe these attacks of pain to be of hysterical origin. Drastasis at the linea alba has also been attributed as a cause of umbilical colic, but is now known to be a purely physiological manifestation.

*February 3, 10, and 17, 1914.*

**Icterus in Extrauterine Pregnancy.**—Schottmüller refers to icterus gravidarum, which may be due to several causes, as diseases of the biliary passages resulting from calculi or icterus catarrhalis, or to hemolytic icterus, of infectious nature and usually fatal. In many cases the hemolysis causes a degree of hemoglobinuria, and the blood serum contains, as shown by the spectroscope, either methemoglobin or hematin. From these substances the icteric hue is derived, and all icteric pigment is one and the same. After a thorough discussion of icterus gravidarum with normal pregnancy, the author comes to the same phenomenon in extrauterine pregnancy. But few such cases are upon record. In 1884 Dick reported cases in which icterus and urobilinuria existed side by side. The latter he ascribed to the absorption of blood. While such an increase in the urobilin of the urine may occur, it is a mistake to look upon the icterus as having this origin. In the author's cases the spectroscope showed in the blood hematin but no urobilin. In 1909 Lodowijks reported icterus in ectopic pregnancy and Michaelis and also Tauber hemoglobinuria in the same condition. The main question of course is as follows: Are we able to diagnosticate ectopic pregnancy through certain icteric pigmentations? The great difficulty in diagnosis of this condition makes welcome any additions to our resources. The author cites a case in point: A woman in the third month of gestation began to suffer from violent stomach pains. Diagnosis, cholelithiasis; later jaundice began to appear. The patient gradually went to pieces. Not until two weeks' delay was an interperitoneal hemorrhage suspected. Laparotomy in the dying revealed a ruptured tubal pregnancy. This case could doubtless have been saved if the hemolytic nature of the icterus had been established. In ruptured ectopic pregnancy the absorption of blood is marked by the appearance of urobilin in the urine. But this happens under various conditions, and often does not happen at all. Sometimes during menstruation we see a jaundice due to uterine hemorrhage. The author concludes that hemolytic icterus (or hemato hepatogenous icterus) or in other words hematinemia may be a symptom of present extrauterine pregnancy, and possess diagnostic significance.

**Inguinal Pain in Young Men.**—Spoerl reports an affection seen by him in several dozen cases, almost invariably in men in their twenties. These subjects believe themselves to be victims of real or prospective hernia and in that state of mind look up the medical man. As a rule they have already provided themselves with trusses, which so far from lessening the pain often increases it. The pain is described as a traction or twitching in the groin. Examination reveals a negative result, but there is a tenderness in and about the external inguinal ring. The author has assumed that the pain is seated in the spermatic cord and connected with the preparation and excretion of the semen—patients are always men in the stormy years of sexual maturity. The author treats these cases with belladonna per os or suppository with massage of the groin and bromides. A more direct plan is Braun's infiltrating anesthesia (novocaine-adrenalin). The pain may be ascribed to a colic of the spermatic cord, combined with a neuralgia in the realm of the external spermatic nerve involving the nervous genito femoralis. The first of these passes through the external inguinal ring along with the spermatic cord. The original pain is due to the pressure of the latter, swollen by the intumescence of puberty, against the nerve already mentioned. The truss is discontinued entirely.

**Impulse of the Blood Column in the Subclavian Arteries as Sign of Aortic Sclerosis.**—Trunecek has made the observation that with hardening of the aortic wall the subclavian arteries become the seat of a special pulsation. The latter is explained as follows: The normal circulation is made possible because the left ventricle propels a certain quantity of blood into the aorta. When normal the latter is distended for an instant but its elasticity causes it to resume its normal caliber. But if the aorta is hardened this change in volume becomes less marked and finally ceases altogether. The amount of blood thrown into the aorta and finding no room, becomes felt in the aortic branches. The subclavian arteries which are given off transversely from the aorta feel the impulse chiefly on the upper wall, so that the finger laid upon the vessel feels the peculiar pulsation, which is of course synchronous with the ordinary pulse beat. Through its intensity and diffusion, one may recognize the degree and amount of aortic sclerosis. The "sclerotic impulse" is as a rule readily recognized and is alone sufficient for diagnosis of aortic sclerosis. This subclavian pulse as found in this condition is not a new affair, for Faure described it in 1874. It differs from the ordinary pulse in degree. Sometimes distinctly visible in the supraclavicular fossa it is so strong as visibly to lift the finger laid gently above it.

**Blood Finds in Whooping Cough.**—Schneider sums these up as follows: In this affection there is a constant blood picture, expressed as follows: A general leucocytosis, up to the third week (usually equivalent to the acme). The normal value is increased to an average of 27.100, which after recovery becomes normal. Variations are noted in individual cases, especially with complications, so that in extreme instances the above figure may be quadrupled. The lymphocytes remain increased during the first four weeks, ranging from 58 to 63 per cent, although exceptionally much higher. The large mononuclear and transition forms are slightly increased (never above 10 per cent.). The blood finds have no prognostic significance.

**Thyroid Treatment of Hemorrhagic Metropathies.**—Schot cites 25 cases of metrorrhagia in which there were symptoms of hypothyreosis. The hemorrhage was pure, due to no local cause. These he treated with thyroid extract or substance. The cases seem to be examples of menorrhagia. When the use of the remedy was suspended there was a certain tendency to recurrence, necessitating a return to it. In endeavoring to arrive at the best dosage, blood controls were employed, as the deleterious action of excess of thyroid is present here as elsewhere. On the other hand occasional improvement in other respects than menorrhagia were noted. Here belong the results of autointoxication, spastic obstipation, and nervous disorders.

**Indifference to Adrenalin Action in Dementia Præcox.** Schmidt has tested thirty-four cases of dementia præcox in regard to the action upon them of the drug adrenalin with special reference to blood pressure.

As a result they were found to be for the most part insensitive to the action of the drug—either there was no effect whatever on the blood pressure or but a minimal one or at most a very slight one. The highest increment was about 18 mm. The usual valuation of the entire blood pressure was from 40 to 80 mm. Striking it was that the more pronounced the clinical picture the greater the degree of insensitiveness to adrenalin. Example: a medical student was admitted to the clinic in a state of severe katatonic agitation. He had in a peculiar fashion mistreated his wife and child. He showed in the clinic stupor alternating with excitement and all the symptoms of katatonia. After several months of intenation in an asylum he was discharged as relatively cured. During this entire period he was tested with adrenalin, and no rise of blood pressure was ever noted—in fact a sinking was often in evidence. As soon as the katatonic syndrome (negativism, automatism upon command and flexibility) abated, the insensitiveness of adrenalin began synchronously to disappear. Upon discharge 0.5 gm. adrenalin was able to increase blood pressure by 20 mm. Hg.

**Self-Accusation and Pathological Conditions.**—Heilbronner discusses this subject at length. Self-reproach is associated in the mind of the psychiater with depressive mental disturbances and notably in pure melancholia, although in but a small percentage of cases. The so-called "angotmelancholie" is often seen in the early stages of chronic progressive psychoses. These subjects have hallucinations of crimes committed and give themselves up to justice. In hallucinations of hearing, a man may hear accusing voices. This behavior is frequently seen in alcoholism. Self-accusation was once held to be evidence *per se* of mental alienation, or at least to cause suspicion of the same. But an innocent may pose as a guilty party to save another if family pride is involved, and submit to prison sentence or heavy fines. A criminal may confess to a lesser offence in order to avoid suspicion of a greater crime. The author does not allude to self-accusation as a means of securing free transportation to some place in which a crime has been committed, nor to similar confessions from other motives, perhaps regarding these as beyond the pale of his article.

**Salvarsan Deaths.**—Kohrs reports a case in which death occurred in about three days after an injection, with symptoms of acute encephalitis. The case was unusual in that the patient appeared to be perfectly healthy and unusually robust. The dose was 0.6 gm. and was given as a result of a Wassermann positive. This test was made because of the presence of a balanitis, and on account of this find the patient received a full inunction cure. But one intravenous injection of salvarsan was given, hence the impossibility of anaphylaxis. The clinical picture was the same as is usually seen in salvarsan deaths of this type and together with the autopsy finds indicates that arsenic has broken loose from its molecule and acted by itself in its ordinary toxic capacity. While clinically arsenical poisoning is not imitated closely for obvious reasons (intravenous injection) the autopsy finds correspond entirely, as far as the brain, kidneys, etc., are concerned, with ordinary arsenical poisoning. Epileptoid convulsions were a feature of the encephalitis and doubtless contributed very largely to the death.

---

**Deutsche medizinische Wochenschrift.**

*February* 19, 1914.

**Rapid Removal of Subconjunctival Hemorrhages and Suggillation of the Lids.**—Mohr refers to cases of this sort "innocently" acquired, in the course of coughing, straining at stool, etc. These subjects are often falsely accused of fighting or alcoholic debauchery, and no treatment is generally presented for such lesions. The author practises a subconjunctival injection of a 2 per cent. to 3 per cent. sterile saline infusion, repeated at intervals; while at the same time dionin solution 5 per cent. is instilled into the conjunctival sac. A few hours should elapse between the exhibition of the two substances. Novocain should first be used, but does not always prevent after-pains. The results of the treatment is absorption of all extravasated blood in two days. Should the case be of traumatic origin the same treatment is pursued. The author is silent as to the cosmetic component and the fact that skilful "make up" readily disguises lid suggillations should be borne in mind in this connection.

**Penis Duplex.**—Lionti reports an illustrated case of this malformation, from which it appears that mating with a woman with vagina duplex, which has been suggested as the natural way out of this dilemma, is chiefly speculative and not practical. The organs differ much in size and length and are separated by a raphe, like the two halves of the scrotum. Coitus with a normal woman was naturally out of the question, so that an extirpation of the lesser penis was the sole remedy. This was done without much difficulty. From the terms "accessory" and "supernumerary" penis applied to the portion removed it is not clear that the case is one of penis duplex in the strict sense of the word. This accessory organ had no functional importance, there was a very shallow meatus, but no patent urethra. Urine and semen passed through the major penis alone. Nothing is said as to the eligibility of the lesser penis.

**Septic Anemia.**—Knauth reports a fatal case of this more or less occult affection. A soldier was seized without apparent cause (aside from a recurring tonsillitis) with great prostration, vertigo, vomiting—or rather an inclination thereto. In this state he was admitted to the garrison. Upon admission the most striking symptom was acute anemia, the only cause of which appeared to be hemorrhage of the intestines. Transfusion was at once practised and with immediate improvement. This only enabled the patient to hold his own, however, and an attempt was made to nourish the patient through a jejunal fistula. Death, however, was inevitable. Autopsy showed a number of interesting finds: pus in the left tonsil; small ulcers and hemorrhages in the stomach; polypi throughout the intestine; bone marrow showed degenerative anomalies; the spleen contained an abundance of staphylococci. The rationale of the case was in the highest degree complicated. Tonsils attacked with staphylococcic inflammation. Cryptogenetic sepsis with resulting hemolysis causing part of the anemia. Some actual escape of blood from the intestine owing to presence of polypi. This loss in the absence of the toxemia would doubtless have been trifling. The tonsillar lesion was undoubtedly chronic.

---

**Case of Friedreich's Disease Following Diphtheria.**—J. Taylor reports the case of a man, aged, 21, who was admitted to the hospital December, 1907; discharged March, 1908; diagnosis, "postdiphtheritic ataxia." Readmitted October 31, 1913. Had diphtheria in April, 1907, followed apparently by postdiphtheritic paralysis—diplopia, regurgitation of fluids, weakness in legs, difficulty in walking. Now has ataxia. Knee-jerks not obtained. Plantars: Right doubtful, left extensor. Articulation peculiar; tremor; no nystagmus; slight scoliosis. No deformity of foot, although left foot different from right. Family history negative.—*Proceedings of the Royal Society of Medicine.*

## Insurance Medicine.

**The Prognosis of Traumatic Neuroses in General.**— Billström of Stockholm states that Oppenheim and with him most of the German authors regard the prognosis of traumatic neuroses as bad. Of Oppenheim's cases not one has been cured, and but seven have shown an essential improvement, although most of the subjects were controlled during an ample time. Of eleven patients cited by Nonnes, one had disappeared, one had committed suicide, eight after an eight-year period of observation showed no improvement, while but one showed improvement. Bruns believed that if all monosymptomatic cases should be classed together the prognosis would be made better than is really the case. Charcot emphasized that the prognosis of traumatic neuroses is worse than that of other kinds. Crocq made a distinction in prognosis between neuroses from head wounds and those without this causation, deciding prognostically in favor of the latter in part. A series of French writers hold that the prognosis is good. Numerous statistics are available—those of Oppenheim, Schultz, Hoche, and Putnam, for example—which show great variation. Putnam obtained by far the best figures —only 22 per cent. negative results. The statistics presented by the other reporters show that the negative results have varied from 30 per cent. to 80 per cent.

There is another mode of calculating these results, to wit, the earning capacity after injury. Thus, of Nægelis' 138 cases complete efficiency was present in 115, partial in 20 cases. The dissimilarity in all these results is explained by the fact that the prognosis in these cases is essentially good, but is made worse by a number of factors. Some of these have been considered, but others cannot be determined and are grouped together under personal equation. Under certain presuppositions one may say that the prognosis is good, and as for the mild grade of invalidism in cases of traumatic neurosis the method of indemnification in private insurance societies—cash for six months without invalidism allowance—is ideal, and should be adopted by Imperial Insurance Associations, and is best for traumatic cases.

Not only from the etiological viewpoint, but also from the prognostic (Crocq, Sachs), which separates traumatic neurosis due to trauma capitis from other species, both upon practical and technical grounds, must the latter be regarded as a special group. The prognosis is better than one is inclined to assume, and one may say that for true traumatic neurosis, at least in Sweden, the prognosis is good (over 90 per cent.), if regarded from the social viewpoint. Considered neurologically the prognosis is always doubtful. Along with an increasing period of observation the number of recoveries always increases.

Local and monosymptomatic forms of hysteria and neurasthenia give the best prognosis. When there is hereditary taint, low intelligence, high age, alcoholism (after injury), arteriosclerosis, etc., prognosis is made worse, but not absolutely bad. The social *milieu* acts both ways—for the better or worse, according to the case.

Repeated accidents are of the greatest importance, because they seem to indicate a sort of predisposition for traumatic neurosis, while in certain cases they represent relapses. The kind of injury is also of influence on the prognosis, but a relation between the localization of the injury—save head and perhaps back injuries—and the prognosis has never been found by the author.

The written opinion has a bearing on prognosis and should not be shown the patient. A general prognosis in regard to ultimate cure may be given as good. The compensation given seems to affect the prognosis, and the statute that these subjects are not to be regarded as invalids seems to have a counteracting effect. Litigation impairs the prognosis and indemnification save in the capital cases, when the reverse may be seen.—*Zeitschrift für Versicherungsmedizin*, October, 1913.

**Types of Mortality Tables.**—Mr. Franklin B. Mead, Secretary and Actuary Lincoln National Life, in discussing the three types of mortality tables, namely, the select, aggregate, and ultimate, or more properly speaking, the truncated aggregate, points out that an aggregate table of one generation may be in effect an ultimate table for the next, due to a general improvement in mortality and in the selection of risks, and cites the actuaries' table as a well-known example of this. The most refined table is the select, and probably the most satisfactory from most standpoints. The premium rates, according to it, must be loaded for adverse deviations in mortality in addition to being loaded for initial and renewal expenses. The ultimate table is highly satisfactory for all practical purposes and unquestionably the safest. As far as can be seen, in American practice, it will be used for the calculation of premiums and reserves.

Mead further states that the effects of selection are permanent. As, for instance, the elimination of many hazardous occupations, risks of general low grade, and the elimination overweights. Extra mortality on overweights increases with age and duration of years for a long period, and the elimination of such risks affects the ultimate mortality for thirty, forty, or fifty years or more.—Medical Section, American Life Convention.

**Health Work of Insurance Companies.**—About $3,000,000 was spent last year by fraternal organizations, labor unions, and insurance companies in special funds for the treatment of their tuberculous members and policyholders, according to a statement issued by the National Association for the Study and Prevention of Tuberculosis. Sanatoria for the care of tuberculous members of such organizations have been established by four fraternal orders.

Among the labor unions, the Printers and the Printing Pressmen are the only two national bodies having tuberculosis sanatoria, the former at Colorado Springs, and the latter at Rogersville, Tenn. An active propaganda against tuberculosis among their members is carried on also among the Cigarmakers' Union, the National Brotherhood of Operative Potters, the Photo-Engravers, and several other similar groups. In some of the unions funds are set aside for the care of sick members.

Insurance companies are also engaged in a tuberculosis campaign. The Metropolitan Insurance Company is building a sanatorium at Mt. McGregor, N. Y., and is spending large sums every year in caring for its sick policyholders. The Equitable, Prudential, Postal and several others of the large companies are carrying on active educational campaigns among their policyholders.—Bulletin of the Chicago School of Sanitary Instruction.

# Book Reviews.

Précis de Coprologie Clinique. By Dr. René Gaultier. 2e Edition. Price 12 francs. Paris: J. B. Baillière et Fils, 1913.

This book on stool examination appears in its second edition. It is modeled upon the same plan as the first, with numerous additions made necessary by recent advances in this department of medicine.

It is a book profusely illustrated and at the same time full of original thought, because it is not merely a compilation, as so many of its kind, but a thorough presentation of the author's own methods as well as those presented by Max Einhorn, Adolf Schmidt, Ricardo Lynch, Combe, Triboulet, Enriquez, Ambard and Sinet, Monges, J. Ch. Roux, Riva, Griffon and others, methods that were tried out by the author in his work and found of service.

Didactic in its first part, the book presents, without any superfluities, all the physician ought to know in this special branch to enable him to examine stools in a satisfactory manner; the second part is entirely clinical.

In regard to the formation of gas in the intestine the author says:

"We have already seen that the gases from the large intestine, evacuated per anum between the stools, are very similar to those produced from the stools by slow putrefaction; for, if it is true that a good many gases, products of abnormal intestinal fermentation, may be absorbed by the mucous membrane, it is also a fact equally constant that these, by the irritation they produce, are accompanied by more frequent evacuations, in which by estimation of the gases the intensity of the processes, occasioning them, can be gauged. We can thus, by the methods previously indicated, arrive at conclusions as to the influence of food and as to the diseases of the digestive tract.

"The intensity and variety of the gas depend on various factors, as the quantity and quality of the food, functional disturbances of the digestive organs and abnormal microbial pollution."

In this work practical deductions are made as to diet from the examination of the stool. Gaultier further treats of digestive insufficiency, due either to deficient mastication or to gastric intestinal, or pancreaticobiliary insufficiency. He gives example of rational dietaries, of the therapy of biliary and pancreatic affections, of duodenal dyspepsia, of constipation, and of diarrhea, particularly of acid diarrhea and tuberculous diarrhea which the author has specially studied.

The volume can be highly recommended as a work of reference in which physicians can find ample information as to these diseases.

Beriberi. By Edward B. Vedder, A.M., M.D., Captain Medical Corps, U. S. Army. Member of the United States Army Board for the Study of Tropical Diseases as they Exist in the Philippines. The Cartwright Prize of the Alumni of the College of Physicians and Surgeons, New York, for 1913. Price $4.00 net. New York: William Wood & Company, 1913.

For many years the subject of beriberi has been one on which it has been difficult or impossible to obtain any definite information. Claims and counterclaims have collected in large numbers and the enormous mass of literature has been increased by numerous polemics. Now and again the discovery of the cause of the disease has been announced only to be discredited on further research. It is perhaps rather difficult for the physician in the East to appreciate the importance of this disease on the western shores of the Pacific. But there the interest is acute and a great deal of excellent work has been accomplished. This volume presents the work of the Army Board as set forth by a man who has spent more than two years investigating the disease in the Philippines. Beginning with a discussion of the history, distribution, pathology, and symptomatology of beriberi and a chapter on rice and its preparation for food, the main portion of the book is devoted to a critical examination of the facts concerning etiology. One by one the various theories and explanations are considered and their falsities demonstrated. Vedder shows very conclusively as a result of both laboratory and clinical investigation that beriberi is caused by the deprivation of some substance which is deficient in certain kinds of food and which is present in the hull of the rice grain. This substance has actually been isolated and has proved to be a crystalline organic base which has been called "vitamine." Feeding of the vitamine brings about cure of the disease or prevents its development. The vitamines are present not only in the rice hulls, but also in certain beans and in many other foods. The necessary correction in the dietary of the Philippine Scouts has resulted in the complete elimination of this disease from this organization and the Japanese Army and Navy have also been protected by a proper diet. The subject is handled thoroughly and attractively and an exhaustive bibliography is appended. The volume is a valuable one and is well worth the award of the Cartwright Prize and reflects additional credit, were it needed, upon the medical department of the United States Army.

Causes and Cures of Crime. By Thomas Speed Mosby, Member of the American Bar; former Pardon Attorney of the State of Missouri; Member of the American Institute of Criminal Law and Criminology; Author of "Capital Punishment," "Youthful Criminals," "Alcoholism and Crime," "Mothers of Bad Boys," and other essays. Price $2.00. St. Louis: C. V. Mosby Company, 1913.

The author believes that the suppression of crime is not at all a legal question, but rather a problem for the physician and the economist. In discussing the etiology of crime he considers the cosmic, the social, and the individual factors, and while giving to the first two factors their due weight in the causation of crime, he emphasizes the individual factor as by far the most important. There are chapters reviewing the present status of eugenics and asexualization. In the chapter on education the writer arraigns the present educational system as failing to fit children for practical life and urges a system that shall train the whole child—heart, hand, and brain. The third part of the volume is devoted to the therapeutics of crime. The theory of punishment, the indeterminate sentence and parole, and the new penology are reviewed with the purpose of showing that the indeterminate sentence and parole are highly practical and that the reformatory system is far preferable to the penal. The style is simple and concise and the book presents interesting and instructive reading for the average layman as well as for the criminologist.

Chirurgische Technik zur Normalen und Pathologischen Physiologie des Verdauungsapparates. Von Adolf Bickel, M.D., and Gerhardt Katsch, M.D. With Six Plates and Numerous Illustrations in the Text. Mit 6 Tafeln und zahlreichen Textfiguren. Price 12 Marks. Berlin: August Hirschwald, 1912.

In order to afford a proper demonstration of physiological and surgical procedures as they relate to the digestive tract, the employment of animal experiments is necessary. Pavlov, a classical originator of these methods, was the first to call attention to the necessity for a proper knowledge of such technical procedures. There is a demand for a well-illustrated manual in this field and this demand has been supplied in the little work by Drs. Bickel and Katsch. They present a carefully selected list of typical operations on the digestive tract as they may be carried out in animals. The first portion of the book contains a description of the operating room, the necessary instruments, anesthetics, preparation for operation, and the general technique of laparotomies. The special portion of the book is devoted to the detailed description of various operations on the different portions of the digestive tract. The book presents a very valuable compend for laboratory workers and teachers of both physiology and surgery, and is deserving of a wide circulation. There is no book in the English language of equal value and import.

The Dandridge Volume. Being a series of papers presented at various times in the meetings of the Cincinnati Research Society, and dedicated by it to the memory of its distinguished member, Nathaniel Pendleton Dandridge, M.D. Cincinnati: 1912.

The surgeon to whom this collection of medical scientific papers is dedicated as a memorial was well worthy of the honor done him. Dr. Dandridge shone as citizen, scholar, and physician, and the form in which his memorial is presented would have commended itself to him. The papers themselves are excellent in shape and substance.

TUBERCULIN IN DIAGNOSIS AND TREATMENT. By Dr. BANDELIER and Dr. ROEPKE. Second English Edition, Translated by WILFRED B. CHRISTOPHERSON. Price $4.50 net. New York: William Wood & Co., 1914.

THIS is the second edition of Bandelier and Roepke's book in English and presents the up-to-date diagnostic methods and therapeutic procedures with the various culture products derived from the tubercle bacillus. Part one is devoted to the theoretical aspect of tuberculin reaction by modern authors, which aspect varies considerably from Koch's original theory. The latter laid emphasis on the cellular changes following a tuberculin injection. Hertwig, on the other hand, explains the tuberculin reaction on the basis of the condition of the leucocytes. It would take us too far to mention in this review the various other theories expounded, some clear and others difficult to comprehend. In the chapter on specific diagnosis of tuberculosis the well-known von Pirquet test, Detre's differentiation test, the Moro test, and the intracutaneous tests, with many modifications, are carefully described. Although ten pages are devoted to the description of the conjunctival test, the conclusions are as follows: Because of its uncertainty and the possibility of serious harm, as a rule the conjunctival test is only indicated when a therapeutic measure is dependent on its result, and definite reasons justify its preference to other diagnostic methods.

In this second edition the authors review carefully the more recent attempts at immunization, among which Friedmann's is of course mentioned. After enumerating the names of those who speak favorably of the therapeutic value of Friedmann's product and those who consider the remedy as useless if not harmful, the authors come to the following conclusions: "The results obtained with Friedmann's non-virulent tortoise bacilli at all events call for continuance of the experiments, observing all the precautions necessary in the trial of a new remedy and with careful observation, preferably in a clinical institute. With regard to this protective inoculation we feel bound to call for the most extreme caution on account of the doubts raised as to the nature of Klimmer's non-virulent tubercle bacilli, especially by Piorkowski, who is inclined to consider the so-called 'Friedmann's tortoise tubercle bacilli,' isolated in 1903, as weakened *human* tubercle bacilli."

The value of this second edition has been greatly enhanced by additional plates showing in natural colors the results of cutaneous, percutaneous, intracutaneous, and conjunctival reactions. Rather unfortunate is the translator's persistence in talking of "tubercular" reaction, "tubercular" serum, "tubercular changes for syphilitic," etc. He seems to be entirely oblivious of the fact that a "tubercular" serum would mean that the serum had a pinhead formation, and that there is a form of cutaneous manifestation of syphilis and leprosy which is called tubercular and which has nothing whatsoever to do with tuberculosis. He speaks of a "tubercular" meningitis instead of a tuberculous meningitis, etc., etc. Aside of this little ethymological criticism this second and much enlarged edition, which the authors have dedicated to the great master Robert Koch, represents perhaps the most valuable contribuion that has been made to our present-day knowledge of tuberculin therapeutics and specific diagnosis. The book is beautifully printed and handsomely gotten up, and besides the illustrations already mentioned has a number of charts showing the reactions of old tuberculin, original tuberculin T O A, tuberculin A F, new tuberculin T R, and new tuberculin bacillary emulsion.

THE SENSORY AND MOTOR DISORDERS OF THE HEART—Their Nature and Treatment. By ALEXANDER MORISON, M.D., F.R.C.P.; Senior Physician to the Great Northern Central Hospital; Physician in Charge of Heart Cases to the Mount Vernon Hospital for Consumptives and Diseases of the Chest at Hampstead and Northwood; late Physician to the Children's Hospital, Paddington Green, and to the Marylebone General Dispensary. Price $2.50 net. New York: William Wood & Company, 1914.

IN this volume Dr. Morison, from an experience of more than thirty years of observing the nature and treatment of sensory and motor disorders of the heart, offers suggestions and conclusions. The author while freely acknowledging the value of recent methods of examination in the laboratory and at the bedside introduced by Dr. Mackenzie and his followers, at the same time, is on several points not altogether in agreement with the conclusions reached thereby. He is conservative, but attributes to the nervous system in its relation to cardiac sensibility and motion a greater share than physiologists of the present day think is warranted. Though somewhat of a "laudator temporis acti" and possibly inclined to unduly praise the great men of the past, Dr. Morison has produced a book which is valuable in that it expresses the views of one who has gained a reputation as an earnest student and a keen observer.

ABHANDLUNGEN AUS DEM GEBIETE DER GEBURTSHILFE UND GYNÄKOLOGIE. Mitteilungen aus der zweiten Frauenklinik der Königl. ung. Universität zu Budapest. (Obstetrical and Gynecological Contributions from the Woman's Clinic at Buda Pesth.) Bd. II, Heft 2. Price 6 Marks. Berlin: S. Karger, 1913.

THE present issue of these transactions is devoted entirely to two articles by Scipiades. In the first of these he continues a study already begun and published in a previous number of the relations between fibroids and pregnancy, discussing the complications in labor and the puerperium associated with a myomatous uterus. His material consists of sixty-seven cases which have been carefully studied and tabulated. His conclusions are too extended to be noted in this connection, but the article itself deserves a thorough consideration as one of the most extensive in journal literature. In a second contribution to this volume Scipiades discusses pubiotomy and cesarean section in their relation to delivery in contracted pelvis. In a series of 384 cases of narrow pelvis reported during the past two years, seventy-five per cent. were delivered spontaneously with a maternal mortality of less than one per cent. This monograph also presents in a very succinct form the present-day views of this important question.

GENITOURINARY DISEASES AND SYPHILIS. By EDGAR G. BALLENGER, M.D., Adjunct Clinical Professor of genitourinary Diseases, Atlanta Medical College; Editor *Journal-Record of Medicine;* Urologist to Westley Memorial Hospital; Genitourinary surgeon to Davis-Fisher Sanatorium; Urologist to Hospital for Nervous Diseases, etc., Atlanta, Ga., assisted by OMAR F. ELDER, M.D. The Wassermann Reaction by EDGAR PAULLIN, M.D. Second Edition Revised; 527 pages, with 109 illustrations, and 5 colored plates; price $5.00 net. Atlanta, Ga.: E. W. Allen & Co., 1913.

IN presenting a new textbook to the profession on a department of medicine so replete with the output of brilliant intellects, an author either must have a great message to the world, or bring forth his smaller scientific offerings in attractive garb. This work is admirably written and is intended for the beneral practitioner and medical student, and, therefore, cannot be viewed as a competitor to the exhaustive volumes written for urologists. In the thirty-six chapters the diagnosis, treatment, and management of ambulant as well as surgical diseases of the genitourinary tract are considered. The section on syphilis is sufficiently detailed for the purpose of the work. The technical directions are good; especially praiseworthy is that section on the treatment of acute gonorrhea, in which the "sealing-in" of urethral medicaments is described. This alone is of incalculable benefit to those who must attend acute gonorrhea patients. The addenda contain practical suggestions on the elimination of gastric disturbances produced by the iodides, santal-wood oil, etc. The authors deserve praise for the fair and equitable manner in which they treat that necessary ordeal of practice, the financial arrangement with syphilitic patients, a topic so sedulously avoided by other writers. The artisanship of the book is not as good as it ought to be in view of the excellence of the contents.

THE PRACTITIONER'S PRACTICAL PRESCRIBER. An Epitome of Symptomatic Treatment. By D. M. MACDONALD, M.D., Medical Officer of Health, Leven, Fife. Price $1.50. London: Henry Frowde; and Hodder & Stoughton, 1913.

THIS little book is a convenient pocket volume. In addition to a formulary and dosage table, it contains chapters on incompatibles, emergencies in every day practice, diet tables, and other topics. Those who use the book should remember that the preparations and doses are those of the British Pharmacopœia.

# Society Reports.

## FEDERATION OF STATE MEDICAL EXAMINING BOARDS OF THE UNITED STATES.

*Second Annual Session, Held in Chicago, February 25, 1914.*

THE PRESIDENT, DR. CHARLES H. COOK, NATICK, MASS., IN THE CHAIR.

**Public Health Administration.**—Assistant Surgeon-General W. C. RUCKER, United States Public Health Service, Washington, D. C., stated that morbidity reports of the communicable diseases showed the location of cases which constituted foci from which disease might be spread to the well. The collection of morbidity reports thus made it possible to know where to take the proper precautions for the protection of persons who might be exposed to a given disease, and therefore acted as a prophylactic measure for the community at large. The knowledge of the occurrence of disease made it possible to see that the sick received proper treatment not only from a preventive but from a curative standpoint. Morbidity statistics were of value to the local health officer in that they gave him the knowledge upon which to undertake operations for the prevention of the spread of disease in his particular locality. The United States Government in its work of preventing the interstate spread of disease found that morbidity information was absolutely essential. Three things were necessary to efficient public health administration: First, the man, well trained, well remunerated, full time health officer; second, the power, the intelligent, uniform, accurate law, and the adequate appropriation; third, the knowledge of the location and prevalence of disease, in order that it may be controlled by the cooperative effort of the general public, the medical profession, and the public health administrator.

Dr. JOHN A. WITHERSPOON of Nashville said it was unfortunate that in this country we had never seemingly appreciated the real value of human life. We had never appreciated that public health was a science and one that must be carried on by the very best men of the profession. The science of medicine had developed so thoroughly in the last decade along the lines of preventive medicine that we now had broad gauged, scientific men who could handle these problems. The American people must awaken to a realization of the fact that men must be trained for this work and that politics should not enter into the work of protecting the health of the people any more than it did into our courts.

Dr. VICTOR C. VAUGHAN of Ann Arbor, Michigan, said that since the discovery of the tubercle bacillus in 1882 the death rate from tuberculosis in the United States had been reduced 54 per cent. In the past ten years 200,000 lives had been saved from tuberculosis. A battle in which 20,000 lives were lost would stir the world at the time and would fill the pages of the historian of the future. Preventive medicine in the United States had averaged 20,000 lives a year saved in the last ten years. The average of human life had been increased nearly four years in the last ten years. The average of the human life in the United States to-day was fifty years, and if we were to apply exactly what we knew to-day the average human life in this country would be increased about fifteen years more. Since he began the practice of medicine scarlet fever had been reduced in its death rate from fifty-four per 100,000 in the registered area to six; and diphtheria had been reduced from 117 to eighteen. Complete morbidity statistics would show the people their value, and he thought the people then would be intelligent enough to respond.

**Should Not the Federation of State Medical Boards of the United States Adopt a Uniform Minimum Curriculum for Medical Schools?**—Dr. JOHN L. HEFFRON of Syracuse, N. Y., pointed out that we should have a simple, straightforward statement of what were considered fundamental subjects and an outline for each, giving what were recognized as the essential principles to be mastered, and a standard by which to measure knowledge and power. With such a minimum curriculum, each college recognized by a State as worthy could offer electives in various subjects so that every student could pursue a more extended course in the particular subject which commanded his greater interest. In such a way the university idea of education could be carried out. The formulation of any curriculum should be the work of men trained in the science of education. The very terms of the law by which members of the medical examining boards in most of the States were selected made it impossible for them to be teachers. The purpose of such a law was self-evident. The cause of medical education would be forwarded if this federation should secure the cooperation of specialists in universities and in medical education and, with their aid, formulate a uniform minimum curriculum for medical schools to present for adoption to the various states of the Union, and that this great federation should endeavor to secure such an administration as would really test by practical examinations the knowledge of all applicants for the license to practice medicine.

DR. JOHN K. SCUDDER of Cincinnati doubted the advisability of attempting to adopt a uniform curriculum for medical schools, as the enforcement would have to lie with the individual board, and even then within powers written into the various state medical laws. He thought if this curriculum were hard and fast and not flexible, it would defeat the very object desired, the rational education of the student, and would prove a serious detriment to the already burdened college. Flexibility was the keynote of his argument and continuously holding in mind the teaching of medical students to think and not to make automatons of them, which was unfortunately the trend of modern education.

DR. J. M. BALDY of Philadelphia said that Pennsylvania had no idea of adopting hard and fast rules in the administration of its law. The bureau unanimously agreed that flexibility was the proper and only thing, and it was the only way any law could be intelligently enforced.

**President's Address.**—Dr. CHARLES H. COOK of Natick, Mass., delivered an address in which he outlined a number of measures which he thought would be useful for the Federation in the conduct of its work.

**Some Thoughts on the Standardization of Medical Education.**—Dr. HAROLD C. ERNST of Harvard University said it was unfortunate that the teaching of any important branch of medicine should be under the control of a single individual. The desire for standardization had extended already to an unfortunate extent in the almost universal demand that a candidate for registration to practise medicine should be the possessor of the degree of Doctor of Medicine. This demand ignored the fact that this degree was really of university grade; that it was not a prerequisite to the practice of medicine in the older countries, and that it should not be in this. What the supporters of such a requirement really meant was that the candidate should have a degree in medicine, which should be a certificate of having had proper medical training; whether it was a Doctorate or not was entirely aside from the question. This was a matter of academic standing, pure and simple. The faculty of medicine of Harvard had taken a definite position in regard to the hospital year as a prerequisite to a license to practise. After considering all the facts that could be gathered, a committee of the faculty reported that such a step was not advisable, a strong determining factor in the formation of this opinion being the rule of some of the most important hospitals that their interns must be graduates in medicine and holders of that degree.

DR. ABRAHAM JACOBI stated that the standard of medical education even now should be raised so that when young men were sent out to practise among the people they would know more than preventive medicine. The people wanted to know not only about preventive medicine, but the individual patient wanted to know what this or that doctor had done in a similar case, and whether he could be cured or not. This was just as important, from both a practical and a theoretical point of view, as to consume time in talking about preventive medicine which we did not put into practice.

Dr. N. P. COLWELL of Chicago referred to the decrease in the number of medical colleges since 1904, and said it meant a distinct advance. The diminution from 166 down to approximately 100 medical schools had been largely due to the merging of two or more medical colleges in the various States into one stronger and better equipped school. The decrease in the number of medical colleges had been largely brought about through the voluntary action of the colleges themselves. As to prescription writing, there had been a positive effort made to have medical students write prescriptions for individual cases and to discontinue the method of using numbers, as had been done in the past.

**The Use of the Government Medical Services in Standardizing Medical Education.**—LIEUTENANT COLONEL JOHN R. KEAN, Medical Corps, U. S. Army, spoke of the need of some central examining board which, while determining the competence to practise of medical graduates, might at the same time set a uniform and reasonably high standard of medical education, and confer the right to practise anywhere in the United States. If, therefore, such a board could be appointed by the President of the United States for the examination of officers for the Medical Reserve Corps, of a composition which would insure a high standard of requirement, and the State boards would agree to accept and license, without examination, the holders of Reserve Corps commissions, as was now done by many States for medical officers of the government services, the thing could be accomplished. He considered the composition of the board and the expenses incidental to the carrying on of the work of the organization.

DR. DE WITT G. WILCOX of Boston said that any physician who had given even superficial consideration to this subject would agree as to the absurdity of using forty or fifty different standards for testing the ability of physicians to practise in the United States and its dependencies. The people of Maine did not require any different therapy from the people of Florida or of California. The difficulty had been to find some method by which one board could agree to pass upon all of the graduates in medicine. There were constitutional difficulties in the way of establishing such a national board, whether it be compulsory or optional.

DR. WILLIAM L. RODMAN of Philadelphia said that inasmuch as the constitution of the United States had been amended twice recently, it would not be difficult to amend it so as to establish a national examining board, and when a man had passed such a board he should be given a license or diploma which would be broad enough to permit him to practise anywhere in the United States.

**What Instruction Ought Medical Colleges to Give in Pharmacology and Therapeutics?**—DR. SAMUEL W. LAMBERT of New York said there was a great amount of good in the older materia medica and certainly more good than could be found by the laboratory methods of pharmacology, but there was much that was inert and useless, and it was the duty of the school to select the good from the bad and to limit its teaching to the essential drugs. It should be the duty of an examiner to draw out from the student by presenting theoretical therapeutic problems the first mention of any therapeutic measure, or of any drug, and then to hold the student strictly responsible for an accurate knowledge only of the remedies mentioned and suggested by himself. The same rules could be applied to teaching the newer materia medica. The course of instruction in the laboratory of pharmacology should be given by men who had taken the M. D. degree and who had had hospital training in clinical medicine. The course should include a study of the effect of small doses of drugs upon animals and also the toxicology of larger doses in the same way. Therapeutics should be considered not as a separate department, but as a part of the department of clinical medicine, and that certain instructors should be delegated to present to the fourth year students serving as clerks, such therapeutic problems as may arise in the course of the ward service.

**The Viewpoint of the State Examiner.**—DR. WALTER L. BIERRING of Des Moines, Iowa, said that, considered as an index of the qualifications for medical practice, an examination in pharmacology should constitute one of the best criteria of a candidate's ability logically to apply knowledge acquired in a medical school. Of equal vital influence to the progress of therapeutics was the standardization of drugs, for in this way unity of knowledge was established that formed an important factor in the licensure examination. No opportunity was to be omitted to emphasize the close relation that should exist between the pharmacist and the physician. In the broader use that had been given to the term pharmacology there was included practically all non-surgical or non-operative measures in the treatment of disease. From the original drug treatment it had branched out to include chemo-therapy, organo-therapy, sero-therapy, immunotherapy, the application of various forms of physical-therapy, and perhaps to all this could properly be added psychotherapy. The proper application of physical therapy, the underlying principles of chemo-, sero-, and immunotherapy, could readily be incorporated in questions pertaining to applicable disease conditions, thus permitting a wide range in formulating the questions, yet all with some degree of practical aspects, and thus constituting a marked improvement over some of the methods that had prevailed heretofore.

DR. BERNARD FANTUS of Chicago said there was need for considerable improvement in prescription writing. This could be secured if it were realized that prescription writing could not be taught by lectures and demonstrations; that the students must be drilled in prescribing. He believed that the best results could be obtained if a course on pharmacy and prescription writing was given before the work in pharmacology was taken up. The students should be made familiar in this course with the various classes of pharmaceutical preparations and their prescribing. When the student then entered his course in pharmacology he was ready to write prescriptions from the very beginning, and he ought to be required to write prescriptions for each of the important drugs as they were studied, paying special attention to methods of pleasant and efficient administration. When the student finally advanced to the study of therapeutics he should still be required to write prescriptions now from the standpoint of the effect. If the clinical instructors would do their duty and require students to write prescriptions for the remedies needed by the patients treated in hospitals and in dispensaries, the student would leave the medical college well trained in prescribing. A general discussion followed on a model medical practice act, and also on credentials and the evil of the equivalent.

**Reciprocity.**—DR. J. M. BALDY of Philadelphia stated that the method they had adopted had been to take each individual school and judge it on its own merits, irrespective of the fact that it was in a bad environment of faulty state legislation or poorly administered state laws. Having passed on the school and found it competent, as judged by the legal standards of Pennsylvania, as well as by the enforcement of its standards and by its finished products, they registered that school and were ready to accept its graduates and endorse the licenses which they had received from any other State in the Union, it matters not what State, provided only that that State would do the same with the graduates of Pennsylvania schools. The Pennsylvania law required this. They did not even ask that their estimate of Pennsylvania schools be accepted by the other State.

**Officers.**—The following officers were elected: *President*, Dr. Charles H. Cook, Natick, Massachusetts; *Vice-President*, Dr. T. A. McCann, Dayton, Ohio; *Secretary-Treasurer*, Dr. Otto V. Huffman, Albany, New York; *Executive Committee*, Drs. J. M. Baldy, Philadelphia; Herbert Harlan, Baltimore, and Walter L. Bierring, Des Moines, Iowa.

Chicago was selected as the place of meeting for 1915.

---

## NEW YORK ACADEMY OF MEDICINE.

*Stated Meeting, Held February* 5, 1914.

THE PRESIDENT, DR. WILLIAM M. POLK, IN THE CHAIR.

THE evening was devoted to a consideration of Oral Infection in Its Medical and Surgical Aspects.

**The General Practitioner and the Dentist.**—Dr. C. N. CAMAC presented this communication. He said that four influences had led him to study more closely the relation of the dentist to the general practitioner: (1) The large amount of unnecessary and sometimes harmful work done upon the teeth by dentists; (2) the systemic distrubances of a grave or destructive nature traceable directly to this harmful work or to pus areas in the teeth neglected or overlooked; (3) the statement of patients, with these conditions, that their dentist had assured them that their teeth were "all right," and (4) the ignorance of himself and other internists regarding the teeth as an important focus of infection. He spoke of the many structures, such as the tonsils, the vocal cords, the eye, the antrum, the mastoids, the parotid glands, etc., all of which received the careful attention of the general practitioner, and, if found at fault, were treated or referred to a specialist; but the teeth, in the very midst of, and in some instances in direct contact with, these structures, received but passing examination or were dismissed with the instruction to the patient that he should see his dentist. There were three aspects from which this relationship of dentist and general practitioner must be

considered: 1, the professional; 2, the educational; 3, the clinical. The author believed that the relation between physician and dentist was one of the most important factors in the development of the dental profession. Dr. Camac outlined the development of medicine and surgery and said that dentistry could be traced through somewhat the same phases. At first it was only a tooth-pulling art, but it came to involve all the problems in the development and pathology of the teeth. The dental profession had, however, been seized by three great powers of commercialism, mechanics, and cosmetics. These had held it back from scientific attainments, though it had acquired a world-wide reputation among the laity. By cosmetics the speaker said he meant the unwarranted effort to save diseased and purulent teeth in order to satisfy the patient's vanity. He did not include under this heading the efforts to correct jaw deformities and misplaced teeth. This work might well be ranked with that of the orthopedist. Conservative and temporizing work was safe in the hands of expert dentists only. With the majority of dentists it meant the doing of a large amount of harmful and even destructive mechanical work. Dr. Camac declared that fillings, caps, crowns, etc., built in, on, and around diseased teeth often covered or entrapped masses of sepsis which if in any other part of the body would be the cause of alarm and immediate surgical treatment. The surgeon neglecting to liberate the pus from such areas would make himself liable to severe criticism, to say the least. Dr. Camac quoted Hunter of London as calling such dental practice "not conservative dentistry" but "conservative sepsis." Dentists, Dr. Camac pointed out, were not alone at fault, and he further stated that not all dentists were responsible for this bad practice. The dentist must be given the credit of pioneer work in dealing radically with pyogenic infection in and about the teeth and in the use of radiography in detecting these conditions. The dentist and the internist, through the improved standard of dental work, were coming together more and more in consultation and cooperation, as was shown by the fact that the British Medical Association had a "Section on Dental Surgery" and the Americal Medical Association a "Section on Stomatology." The speaker regretted the lack of dental education among physicians and the lack of preliminary and general medical education among the dentists. He then reviewed the status of dental education in the United States and Canada. About 50 per cent. only of the dental schools in the United States and Canada had a sufficiently high standard to receive recognition by the Regents of New York. Dr. Camac pointed out that this meant that there were a large number of schools giving an inadequate education in dentistry. He added that it, moreover, encouraged incompetency and deceived young men into the impression that they had received an adequate education. He classed this with the deception and fraud which to-day vitiated American business and business methods, and declared that it tended to produce a class of men in the dental profession who could practise only by deceiving the public. Some men naturally took to such deception; others were driven to it by the exigencies of beginning life, and the realization that they had spent their money and the precious years of preparation, and that it was too late to go back or make up the deficiency. The speaker declared that the administrators of such institutions should be subject to investigation and punishment by the federal government as were the managers of fraudulent business enterprises. Fifty or sixty of the dental schools in the United States and Canada, accepted by the University of the State of New York through its regents, Dr. Camac considered in detail. These schools were placed in two groups—those "registered" and those "accredited." In the registered group the requirements were that the applicant for admission be twenty-one years of age or over, of good moral character, and have a general education equivalent to four years in high school, after eight years of elementary preparation and three years' education in a dental school. To the "Accredited" group belonged those schools not meeting these requirements. Of the fifty or sixty schools considered thirty-five met with all the requirements and twenty-two fell into the "Accredited" group. Twenty of these were accredited with only two years. Two dental schools in Canada which received full recognition by the New York Regents as registered schools had a four years course, the speaker went on to say, but in the United States, he added, there were no registered schools with a four years' course. After reviewing the state requirements for those wishing to practise dentistry the speaker concluded that dental education and the requirements for the practice of dentistry were in urgent need of a thorough revision and the raising of the standard. The medical schools should include a course of stomatology with especial reference to the relation of the teeth to systemic diseases. In speaking of the clinical aspect of this subject Dr. Camac deplored the loose way in which the terms indicative of oral sepsis were used in medical literature and by the internist. Works on dentistry dealt very thoroughly with the nature and extent of the local process, but neither these works nor writings upon general medicine recorded the relation of the local conditions to some of the most destructive systemic processes (arthritis, endocarditis, etc.). The author cited a case which showed the necessity for close cooperation between the dentist and internist. This case was typical of the subtlety of these infections, and demonstrated how the infection might remain latent over a long period between the time of the first dental infection and the severe systemic manifestations. He urged the importance of bacteriological examinations by dentists and the preparation of vaccines. He pointed out the necessity for visiting dentists and dental internes upon hospital and dispensary staffs.

**Mass of Tartar Developing Five Teeth.**—Dr. CAMAC showed this specimen. The diagnosis of epulis had been made and the mass was about to be removed when a hospital interne removed it entire with but slight traction.

**Radiograph of an Abscess Beginning in a Lower Incisor and Pointing in the Submental Region.**—Dr. CAMAC presented this specimen in which there was a marked necrosis of the lower jaw. The patient refused to have the diseased tooth removed.

**The Dental Aspects of Oral Infection.**—Dr. M. L. RHEIN presented this phase of the subject. (The paper will be published later.)

**The Surgical Relationship of Oral Infection to Secondary Infection.**—Dr. T. B. HARTZELL of Minneapolis, Minn., read this paper. He stated that the subject under discussion was one that had engrossed his entire attention for several years. It was well known that almost every type of pathogenic organism found its way into the oral cavity sooner or later. Many of them made their permanent residence there. The skin and mucous membrane which protected the balance of the body failed of their office here. This was because the teeth in erupting through the mucous membrane burst that membrane and its continuity was never restored. That mucous membrane ended abruptly about a line below its surface, thus leaving a free margin, creating a delicate crevice which was a door through which could occur inoculation. The bacterial flora on the tooth surface was always great in the mouth of every individual unless special care was given the tooth surface to free it of this bacterial coat. From this bacterial coat incursion might constantly be made into the crevice and thence into the tissues. Thus, as a rule, every individual had, to a greater or less extent, always present on the tooth surfaces at this unprotected margin the potential for the deep infection of the surrounding tissues. In recent examinations of freshly extracted living teeth they had found bacteria distributed for a considerable distance in the peridential membrane where the tissue seemed to be in a moderate state of health and presented no lesion to account for their presence there. Their presence was readily explained when one considered that where the mucous membrane ended abruptly and a line below its surface there were small open channels leading into the vascular network of the tissues. The first effect of this bacterial incursion was to create a mild gingival inflammation. This was succeeded by a more intense cellulitis with the development of pus. The greater part of this pus escaped into the oral cavity, but many microorganisms were driven directly into the tissues by the intermittent application of force in mastication. The intermittent application of force caused the teeth to alternately rise and sink in their sockets. This rise and fall occurred in most mouths thousands of times per day and made it certain that a portion of the infectious material surrounding the tooth in the deep crevice would be driven into the broken blood-vessels and lymphatics of this locality, and these microorganisms went directly into the tissues and small blood vessels in the pericemental structures. These paths led into the circulating blood. The glandular structures became involved and a part of this bacterial growth was carried into the lymphatics and lymph nodes of distant parts of the body. The weight borne in twenty-four hours by the grinding surfaces of the teeth the author estimated at 5,000 pounds per day, and it was this elastic cushion of peridental membrane that permitted the teeth to sink into their sockets and

then rebound which protected the alveolar process from rapid absorption and the teeth themselves from cleavage or splitting. Where osteomyelitis occurred in the bone of the socket, the infected area rapidly increased. The dental abscess occurring around the root ends of teeth with dead pulp was an additional source of systemic infection and the porous character of the bone, together with the constant make and break in the application of force in mastication, enabled the existence of such an abscess, without symptoms of pain and soreness, to drain for months and even years, thus affording a constant flow of bacteria into the circulation. The recent examination of pus from blind dental abscesses had revealed the presence of both aerobic and anaerobic forms of streptococci, and it was this blind dental abscess with the accompanying pyorrhea pocket which eventually broke down the resistance of many individuals, so that when they were subjected to stress of any sort the toxic habit established by these constant streams of infection made it impossible for such an individual to override disease and explained many a case of death from comparatively slight surgical operations. The metastatic possibilities of these seemingly trivial mouth infections had not until recently been apprehended by either the dental or the medical professions. That their importance was greater than had hitherto been apprehended was well illustrated by eight cases of which the author recently had made an intensive study. These cases included four of joint affections which seemed to have been benefited by the administration of vaccines: one case in which fusiform bacilli and streptococci were found in smears from the alveolar process, and in which after death cultures taken from the heart's blood and from the body of the lower jaw also showed streptococci; a case of necrosis of the upper jaw, due to necrosis around the central incisors which spread to the whole palate; a case of failing health in a man sixty-eight years of age, whose urine contained albumin and casts, whose health was greatly improved, the albumin and casts disappearing from the urine after the evacuation of the alveolar abscesses and pyorrhea pockets; and a case with a history of ulcer of the stomach in which complete recovery took place after the removal of abscessed teeth and pyorrhea pockets.

Dr. Henry James said he thought it must be admitted that the average medical man did too often neglect the conditions of the teeth in his search for etiological factors in disease. The excellent papers of the evening had only too well shown the importance and the very intimate relationship this subject held to internal medicine. The studies of William Hunter, whose little book on "Oral Sepsis" published in 1901 showed, as no other work up to that time had done, the various conditions which might be associated with infections of the teeth and gums and had been of the greatest value to him in certain rather obscure conditions which were definitely traced to trouble in these localities. The cases he had seen appeared to resolve themselves into two classes: the obvious and the obscure. The obvious comprised those whose symptoms and physical signs corresponded to some definite disease, such as arthritis, endocarditis, and the toxic gastritis and neuritis of Hunter. The obscure, those which by the variability of their symptoms could be classified according to none of the well established diseases and to which one was at a loss to put a name. In the past two or three years the speaker had been associated with several cases which to him had been interesting and most instructive. There were one or two cases which might be worthy of mention. The first, a middle aged man, whose health began gradually to be impaired with anorexia and extreme asthenia. His blood pressure was continually below 100 mm. and he had marked mental depression. There was at no time any fever or leucocytosis. For a long time he was regarded as a case of Addison's disease without pigmentation. Eventually his teeth were found to have been in very bad condition for many years. There were several roots in pus sockets with advanced Rigg's disease and much suppuration. Six months after extraction and thorough cleansing of the alveoli his health was restored and since that time, now one and one-half years, there had been no relapse. There were two or three others of like type hardly necessary to go into. The speaker said he would like to say a word about the case to which Dr. Rhein referred and whose radiograph he showed. This case first came under his care about two months ago giving a history of chills, fever, and sweats with some dyspnea on exertion. He had had mild arthritic symptoms not severe enough to put him to bed. The physical examination revealed a soft diastolic murmur along the left of the sternum with slight increase to the left of the area of cardiac dullness. Ulcerative endocarditis was naturally suspected and a blood culture showed a sure growth of *Streptococcus viridans*. Regarding the primary focus of his infection, he was questioned in respect to his teeth when it was learned that the radiogram shown by Dr. Rhein had been taken. Another plate was made confirming the presence of a granuloma above the root of the right lower bicuspid. This tooth had formerly been crowned and was to all appearances healthy, nor had it given him any sensations of discomfort whatever, but he was advised to have it out and at the operation a culture on blood agar taken from the socket resulted in almost a pure growth of *Streptococcus viridans*, thereby proving without much question the point of origin of the infection. He is now on sensitized vaccines, the outlook being most unfavorable. These two cases were sufficient to show the importance not only of a diligent search for a probable primary focus of infection in any disease of this nature, but also that of thorough examination of the oral cavity by *x*-rays where such a focus might be suspected.

Dr. Camac thanked Dr. Hartzell for his paper and said that Dr. Hartzell was the type of investigator and his work the kind that would do much to raise the standards and encourage accurate and intensive research work in dentistry. He had stated in his own paper that there were no research laboratories devoted to dentistry. Since hearing Dr. Hartzell he wished to correct that statement. Dr. Hartzell's laboratory represented the best type of Research Laboratory. The speaker said he wished to add two clinical points brought out by Dr. Hartzell. Blood cultures and cultures from joint fluids were in the large majority of cases negative for microorganisms. The finding of microorganisms in the blood was of grave prognostic significance. On the other hand fixation by the blood of organisms found in the gum and tooth cavities and other pus foci was fairly common and proved definitely a relation between the pus foci in the mouth or elsewhere and the system; the preparation of vaccines, therefore, was important, for the purulent infection might subside in the primary focus and yet the system might have developed new foci from which pus could not be obtained and which therefore vaccine alone might reach. Transmutation was a most important factor in this question of cultures and vaccines. Finally, he wished to emphasize the necessity for the early diagnosis of oral infection and the detection of pus areas in any part of the body, as in the deep urethra, the peritonsillar tissues, etc., and declared that the dispensaries were the places to detect the beginnings of destructive disease, the ruins of which they now studied in the hospitals with expensive laboratories and apparatus. Instead of the slipshod hurried work by young physicians, painstaking laboratory and clinical studies should be made on out-patients by trained clinicians.

## SECTION ON OBSTETRICS AND GYNECOLOGY.

*Stated Meeting, Held December* 23, 1913.

Dr. George Gray Ward, Jr., in the Chair.

**Nephrectomy During Pregnancy.**—Dr. Anthony Hart Harrigan reported the case of a woman, 21 years of age, who was admitted to Fordham Hospital January 24, 1913. She was pregnant four months. Her present illness began ten days prior to her admission to the hospital with an alveolar abscess which opened spontaneously. Two days later she had pain in the back and a chill. She had a temperature from 100° to 103.5° F. The pain became general over the abdomen and more severe over the right lumbar region. She was constipated. There was no increase in urination and no burning sensation. The abdomen was moderately distended, and the pregnant uterus was felt. The right kidney was enlarged and tender. There was extreme tenderness in the right costovertebral angle. Examination of the lung, heart, liver, and spleen, as well as the left renal region, was negative. The white blood count was 34,800 and the polymorphonuclears 88 per cent. The specific gravity of the urine was 1030; it contained a moderate amount of albumin but no sugar. There were present a large number of pus cells, and hyaline and granular casts. A diagnosis of infection of the right kidney was made, either a pyelonephritis secondary to a puerperal pyelitis or multiple septic infarcts of the kidney in view of the history of

the alveolar abscess. Nephrectomy was performed. The surface of the kidney presented innumerable foci of suppuration. Recovery was uneventful. There were no signs of kidney insufficiency and the patient did not abort. During the first twenty-four hours following the operation 24 ounces of urine were collected. On the second day 40 ounces were passed and this remained the daily output during the period she was under observation. She was discharged February 16. The pathologist reported that the condition was that of multiple septic infarcts of the kidney, or the so-called unilateral hematogenous infection as described by Brewer. A pure culture of the staphylococcus was isolated. Six weeks after leaving the hospital she was readmitted as her physician feared an infection of the left kidney, but a careful examination failed to reveal any signs of further infection and she was referred back to her family physician. He reported that on May 15, which was about the end of the eighth month of her pregnancy, he induced labor and this was effected without any trouble whatever. A few days prior she complained of itching of the skin and insomnia, and she was very restless and slightly jaundiced. On account of these symptoms labor was induced. The mother and baby were in perfect health.

Dr. L. FRIEDMAN asked if the ureters had been catheterized.

Dr. GEORGE GRAY WARD, JR., said that it was astonishing how much one could do in these cases without bringing on abortion and he did not see why a nephrectomy should produce such a result. Many operations of grave import were done on the pregnant uterus without causing an abortion.

Dr. HARRIGAN replied that the patient was so ill and the kidney infection so apparent that it would have been a waste of time to catheterize the ureters.

**A Simple Form of Perineal Retractor.**—Dr. A. REICH presented this instrument. (See MEDICAL RECORD, November 15, 1913).

**Chorioepithelioma Uteri with Vaginal Metastases.**—Dr. M. CATURANI reported this case. The patient was 27 years of age, had been married six years, and had three children, the last two years previously. In February, 1913, she was operated upon for hydatid mole, after four months amenorrhea. At the end of June she had a severe hemorrhage with abundant passage of clots. She was again admitted to the hospital in a markedly anemic condition. She had had chills, fever, and a very offensive discharge. The uterus was considerably enlarged, moderately contracted, and would not admit the examining finger. At the time the case was diagnosed as one of incomplete infected abortion. After moderate dilatation of the cervix by means of a holder forceps with a small sponge a few pieces of apparently necrotic placental remains were removed. No pathological examination was made of the tissue removed. The condition of the patient improved though the anemia persisted. A few weeks later a small nodule of a dark color appeared on the vestibule and this was removed and sections examined, when it was found that the condition was that of chorioepithelioma. Another vaginal metastases soon formed in the posterior fornix. Hemorrhage, dyspnea, and marked edema soon appeared. The patient died on August 18, 1913, probably from general metastases, with marked pulmonary and cardiac insufficiency. A radical operation would not at any time have been possible. The special point in the history of this case was the amenorrhea following the removal of the hydatid mole. Dr. Caturani said that in a case previously reported by him there was a similar occurrence. In all probability neither patient had conceived after the mole was removed. The amenorrhea could find an explanation in remains of the mole left in the uterus which would be sufficient to influence the ovarian function as a fetal structure in evolution, since following the delivery of the mole the patient's condition was good. This fact would be of great importance from the clinical view point. Amenorrhea, as well as metrorrhagia, should be carefully watched after the removal of a mole, as there was a possibility that the molar remains might give origin to chorioepithelioma. Pathologically the different sections of the original uterine tumor and of the metastases showed the characteristic typical structure of chorioepithelioma. The fact was worthy of note that the uterine curettings were made up mostly of Langhans' cells; in the metastases the syncital cells were relatively numerous, but there were more in the vulvar than in the vaginal sections.

**Lantern Demonstration of Specimens from a Case of Salpingitis Nodosa.**—Dr. M. RABINOVITZ called attention to the fact that the condition known as adenomyosalpingitis or salpingitis nodosa had received practically no attention in this country, probably because the malady was of more interest from the pathological than from the clinical standpoint. The three conflicting views regarding the character of the lesion were: (1) that which held the condition to be inflammatory in origin; (2) that held by Recklinghausen and his school which assumed a congenital origin, due to misplaced embryonic remnants, and (3) compromises between those two views. Many investigators were stimulated by Chiari's studies to search for additional corroboration and prominent among his supporters might be counted Martin, Orthmann, Werth, and Schauta. The foundation upon which Recklinghausen built his theory was the well-known fact that in early fetal life, as soon as the Wolffian body and its canal appeared, the Müllerian duct approached the Wolffian canal, then crossed it, and finally assumed a lateral position. At this crossing point, which was at the isthmian portion of the tube, the epithelium of the Müllerian duct came into so close contact with that of the Wolffian canal that a confluence of tissues readily took place; hence the possibility of Wolffian rests occurring in the wall of the tube. The writer described minutely these adenomatous spaces as being composed of secreting tubules, collecting tubules, terminal tubules, and pseudoglomeruli, all morphological components of the normal Wolffian body. The non-communication of these gland spaces with the tube lumen showed that they were not derived from the tubal mucosa. The presence of yellow bodies or pigmented cells in the lumina of these tubules, mainly the secreting tubules, which according to Mihalkovics, Tourneux, Balabtyne, Williams, and Czerny were constituents of the ep- and par-eophoron also supported this view, as did the ciliated character of the columnar epithelium lining the adenomata. This ciliated epithelium, according to Czerny, was found in the tubules of the organ of Giraldes in the new born sucklings, but disappeared with the advance in growth, and was wanting in even the freshly examined adult specimens. Waldeyer and Orthmann claimed that only the middle portion of the tubules contained ciliated epithelium, while the collecting and secreting tubules were devoid of it. Frey and Krause, on the other hand, described the epithelium lining the organ of Giraldes as squamous in nature. The difference between the staining properties of the epithelium of the tube and that of the gland spaces, the former presenting a deeper hue, which was peculiar to fetal tissue made it probable that the adenomatous spaces were of embryonal origin. The comparative rarity or the total absence of adenomyomatous changes in the cervix uteri was claimed as further evidence in favor of the congenital origin. Why should the cervix uteri, which under normal conditions was so abundantly provided with large glands, be free from adenomyomatous proliferation, while the fetal mucosa, which was ordinarily a glandless structure, be capable of giving rise to glandular metamorphosis? The cases were arranged in two main groups, those in which the adenomyomatous changes were limited chiefly to the mucosa, and those in which the glandular proliferation had extended to and beyond the muscular coats, thus constituting the true picture of adenomyosalpingitis. Dr. Rabinovitz showed twenty-six microphotographs on the screen and concluded as follows: 1. Adenomyosalpingitis (salpingitis nodosa) was inflammatory in origin. 2. It was one of the final stages of microbic infections of the Fallopian tube. 3. The most common microbic infections were the gonorrheal and the tuberculous; in a series recently reported the proportion was as four to one. 4. The theories that adenomyosalpingitis was a congenital or blastomatous process had thus far received no substantiation. 5. The term adenomyosalpingitis best expressed the pathogenesis of this lesion and should be generally adopted.

Dr. HERMANN GRAD said that the microscopic illustrations shown did not convince him that they showed anything of an adenomyoma of the tube. These slides showed to his mind the microscopic picture of a chronic salpingitis where the longitudinal folds of the mucous membrane of the tube had become adherent to each other, giving the appearance of glands. The open spaces shown on the slides which were outside the muscular wall of the tube were uterine glands and he was fortified in his contention by the fact that the microscopic sections were made through the interstitial portion of the tube. The sections of the tube that were

made through the isthmus and ampulla of the tube did not show these glandular structures.

Dr. M. Rabinovitz said that Dr. Grad's conception of the pathology of adenomyoma was apparently not clear, for otherwise he could not have made the assertion that the sections presented by her simply showed the ordinary changes of chronic salpingitis, that the gland-like spaces in the tube wall were prolongations of uterine mucosa, and that some of them were tubal diverticulæ or accessory tubes. Dr. Grad should read through the paper on the "Pathogenesis of Adenomyosalpingitis" and he would be convinced of the unsoundness of his criticism. The lesions in the tubes presented this evening corresponded in all particulars and details to the pathological changes described under this heading by authorities like Meyer, Morton, Werth, etc.

**Ovarian Pregnancy, with Report of a Case.**—Dr. Michele Caturani presented this communication. After reviewing the history of ovarian pregnancy, he cited evidence which led him to conclude that the diagnosis of primary ovarian pregnancy was relatively easy after a careful microscopical study of the specimen. On account of the difficulty of determining the real nature of the cases Williams divided them into positive, highly probable, probable, and doubtful. Up to 1906 he had found only thirteen cases which belonged to the first class and seventeen to the second. Norris, in 1909, reported nineteen cases, and Bryce, Lea, Rubin, Graham, and McCann had each reported one case. The real causes of ovarian pregnancy were rather obscure owing to the rare occurrence of the condition and the unsettled opinion as to the determining causes of ectopic pregnancy in general. The ingenious hypotheses of Webster did not extend to the explanation of those other ectopics occurring outside the tube. He insisted on the decidual reaction as an indispensable factor to the implantation of the ovum, and believed this reaction to be specific to the Müllerian tissue only. Under normal conditions in the human female only the uterus was able to respond to genetic influence. The tube occasionally reacted as a result of some developmental fault, or as a structural or functional reversion of the tubal mucosa to an earlier type in mammalian evolution. When these conditions existed several contributory causes, as the site of fertilization above or below the point of occurrence of the decidual reaction in the tube, would determine whether a fertilized ovum should develop in the tube or in the uterus. As a logical consequence of these views Webster refused to accept the possibility of ovarian pregnancy with the statement that there could be no pregnancy where there was no genetic reaction possible. It was the general consensus of opinion that decidual reaction in the human female was only specific to the uterus in consequence of the functional requirement, and though it occasionally occurred in the tube, it was never complete as in the uterus. There was no reason to believe that this reaction was a primary cause of ectopic pregnancy in the tube, but it was more logical to regard it as a result of the specific action of the fertilized ovum in a tissue homologous or phylogenetically analogous to the submucous layer of the uterus. It should also be remembered that ectopic pregnancy was a pathological condition and hence only pathological factors were worthy of consideration in studying its etiology. The essayist reviewed the various theories advanced as to the etiology of ovarian pregnancy and stated that he had made a most careful study of various sections and had found what might be termed an attempt at decidual formation. There were here and there scattered groups of cells of decidua-like nature, especially around the blood vessels. There was no evidence of decidual cells in any part of the fibrillar connective tissue covering the columns of the luetine cells or the fibrous septa of the same columns. If they considered the decidua as a barrier to the invasion of the fetal tissue, they could easily explain for its insufficient formation the considerable invasion of villi and chorionic cells in the ovarian stroma and in parts quite distant from the fetal tissue. These pathological facts stood against the statement that many cases considered ovarian went to term probably on account of the greater accommodation of the ovarian tissue. If they had to accept as primary the implantation of the ovum in the ovary, they could not but admit that the fertilization was ovarian also. Clinical data, supported by anatomical findings and the opinions of the majority of authors tended to attribute great importance to inflammatory processes of the tube as etiological factors of tubal gestation. The resistance of ovarian tissue to rupture by the ripening follicles and the subsequent formation of cystic conditions was familiar to all. It was quite possible that the opening in the mature follicle might be insufficient to allow the exit of the ovum, or incidental disease of the granulosa of the thecæ folliculi rendered impossible the escape of the ovum. The case reported gave a history of gonorrheal infection and of tubal ectopic gestation on the right side previous to the ectopic reported which occurred in the left side. Evidences of inflammation were clearly shown in the tube and ovary. The symptomatology was typical of ectopic gestation and offered nothing of special interest.

The patient was 33 years of age and had been married twelve years. She had had three children and five miscarriages, and had been infected with both syphilis and gonorrhea, the latter fifteen months before the first ectopic. Dr. Caturani said he had operated on her in June, 1909, removing the right tube and ovary. In January, 1912, she missed a period and in a few days showed all the symptoms of ectopic gestation. At operation, fifteen days after the initial shock, the abdomen was moderately filled with free clotted blood, clots around the left adnexa, but no distinct hematocele. The fimbriated end of the tube was open, but there was no trace of rupture in the tube. The ovary was apparently damaged and was covered with clotted blood. The tube was removed and one-third of the left ovary was resected on the distal pole. This resection was necessary on account of the absence of the right ovary. The condition was diagnosed as one of hematoma from rupture at the site of the follicle, the real nature of the condition not being discovered until microscopical examination was made. The gross specimen was made up of the left tube and part of the left ovary, still attached to the tube by a slight band of tissue. There was no marked enlargement at any point. The ampulla was thickened and hard, but there were no kinks or traces of rupture. Comparing the gross appearance with the microscopical findings the ovum seemed to be deeply embedded about one-half em. in the ovarian substance. Careful study of the macroscopical and microscopical findings led to the following conclusions:

1. The evidence established without any doubt the primary ovarian nature of the gestation. 2. The intimate relation of fetal tissue and corpus luteum in the various stages might be proof of the embedding of the ovum in the follicle. 3. Probably the formation of the corpus luteum partly assumed the function of the decidua only as a preventive of the invasion of the fetal elements. This view was in marked contrast to the views expressed by Bryce and Teacher, and with the behavior of the decidua and chorionic elements in their interlacing in the implanation site. 4. Decidual formation was only present as an incomplete attempt in the ovarian pregnancy, and as a result of the reaction of the stroma to the specific action of the ovum. Every connective tissue in the genital organs was probably able to react in the same way as the Müllerian to the genetic influence. 5. The incomplete formation of the decidua explained the tremendous invasion of the stroma and its surroundings with chorionic elements. 6. This last condition was the cause of the early interruption of ovarian pregnancy.

Dr. Hermann Grad said that the doctor had made a very careful report of this case of ovarian pregnancy and he should be congratulated on this very interesting work. The question resolved itself, in speaking of an ovarian pregnancy, whether Webster's hypothesis was or was not correct. Could the impregnated ovum engraft itself on anything but the tissues of the Müllerian ducts? If not, then was it not possible that "rests" of epithelial cell might become dislodged in the ovary and the fecundated ovum engraft itself on these "rests" and in turn these displaced cells themselves become destroyed by the trophoblast, leaving no trace of their former existence? In this way one could explain an ovarian pregnancy on the hypothesis of Webster. Perhaps the connective tissue of the ovary was capable of reacting towards a fecundated ovum in such a way as to favor its embedding.

Dr. Rabinovitz said that Dr. Caturani had presented a very interesting specimen and his paper had covered the literature on ovarian pregnancy most thoroughly. The etiology of ovarian pregnancy offered a wide field for speculation and theoretical reasoning, but one

must not lose sight of the clinical facts, namely, that most of these cases gave a history of preceding inflammatory affections of the genital tract. She believed that the most potent factor in the etiology of ovarian pregnancy was a preceding perioophoritis causing a thickening of the germinal layer and thereby preventing the escape of the impregnated ovum.

# State Medical Licensing Boards.

## STATE BOARD EXAMINATION QUESTIONS.

### Louisiana State Board of Medical Examiners.

*October 27, 28, and 29, 1913.*

*(Concluded from page 460.)*

GYNECOLOGY.

1. Name the different malignant neoplasms of the ovary.
2. (*a*) What symptoms and signs would lead you to suspect carcinoma of the body of the uterus? (*b*) Why is carcinoma of the body of the uterus less malignant than carcinoma of the cervix?
3. Name the muscles of the female perineum which may be torn during labor.
4. Describe the pathology of cystocele and of rectocele.
5. Name the causes of dysmenorrhea.
6. Differentiate between incomplete abortion and extrauterine pregnancy.
7. Name the different varieties of uterine fibroids.
8. What general and local conditions may cause amenorrhea.
9. Describe the operative treatment for prolapse of the uterus.
10. What symptoms may follow retroversion of the uterus?

SURGERY.

1. Give treatment of a compound fracture of humerus.
2. Give symptoms and treatment of tuberculous hip joint.
3. What operative measures may be indicated in exophthalmic goiter?
4. Differentiate between enlarged inguinal glands, hernia, and hydrocele.
5. Give diagnosis and treatment of epithelioma of lower lip.
6. Give symptoms of acute osteomyelitis.
7. Describe the operation of posterior gastroenterostomy. of the upper jaw will be demanded." (DaCosta's *Sur*-For what condition is it most frequently performed?
8. Give symptoms, diagnosis, and treatment of tuberculous kidney.
9. Give signs, symptoms and treatment of depressed fracture of skull.
10. Describe Colles' fracture. How is it generally produced and how should it be treated?

HYGIENE.

1. How does the expired air from persons differ in its composition from ordinary air?
2. Name at least six bacterial diseases in which the respiratory tract is the portal of entrance for the microorganism.
3. What are the advantages of pasteurized milk?
4. What is the specific gravity of normal cow's milk, and to what is it due?
5. What is understood by active and passive artificial immunity?
6. What is the value of temperatures and sunlight as physical disinfectants?
7. What is understood by an intermediary host in the transmission of infection, and give examples of diseases transmitted in this manner?
8. What measures must be instituted in the prevention of bubonic plague?
9. What is a diphtheria carrier, and what precautions should be observed with regard to the carrier and the community?
10. Which is preferable, the combined system of sewerage and drainage or the separate system, and why?

## ANSWERS.

GYNECOLOGY.

1. Malignant neoplasms of the ovary are: Carcinoma and sarcoma.

2. *Cancer of fundus of uterus* is diagnosed by the presence of tumor, cachexia, hemorrhage, pain, and offensive discharge; microscopic examination may aid in the diagnosis.

*Carcinoma of the cervix* is more apt to spread to the vagina, bladder, ureters, and surrounding tissues; also its lymphatics are larger than those of the body of the uterus, and so metastasis is more frequent.

3. *Muscles of the female perineum which may be torn during labor:* Constrictor vaginæ, transversus perinei, and sphincter ani.

4. "*Cystocele* is really a hernia of part of the bladder into the vagina, the vaginal mucous membrane forming its outer covering; or it may be expressed as a deflection of the vesico-vaginal septum toward the vagina. It forms a smooth rounded swelling, which bulges through the vulvar aperture when the patient coughs or strains.

*Rectocele* is a hernia of the rectum into the vagina, covered by the mucous membrane of the posterior vaginal wall. It forms a swelling resembling that produced by a cystocele, except that it is on the posterior aspect of the vagina. If the finger be introduced into the rectum it can be passed into the pouch in the vagina, and similarly a sound introduced into the bladder can be passed into a cystocele. A rectocele is nearly always associated with a deficient perineum; and, further, cystocele and rectocele are often found together. When this is the case the vulvar outlet, when patient strains, is occupied by two smooth swellings placed one in front of the other; between them the finger can be passed up to the cervix."—(Sutton and Giles' *Diseases of Women.*)

5. *Causes of dysmenorrhea:* Pelvic congestion, pelvic inflammation, malnutrition, overwork, lack of development, neuralgia, stenosis or obstruction of the cervix, prolapse or displacement of the uterus.

6. In *incomplete abortion,* there is persistent hemorrhage, which may become offensive; the cervix is dilated, and membranes or decidua or clot may be felt; the uterus is large and soft.

In *extrauterine pregnancy,* there will be signs of early pregnancy, hypogastric or inguinal pains, probable history of a previous sterility, probable expulsion of decidual membrane of shreds, softening of the cervix, enlargement of the uterus, presence of a distended tube, contractions of the wall of the gestation sac; if rupture occurs, there will be sudden excruciating pains over the lower abdomen and on the affected side, shock, collapse, and symptoms of internal hemorrhage.

7. Fibroids. *Varieties:* (1) Subperitoneal or subserous; (2) interstitial, in the uterine tissue; and (3) submucous in the endometrium.

8. Amenorrhea is *physiological:* Before puberty, during pregnancy and early lactation, and after the menopause. It may also be due to: Absence or imperfect development of the generative organs; also to operative removal of the uterus or its appendages. Other causative factors are: Acute infectious diseases, anemia, chlorosis, obesity, drug habits, alcoholism, overstudy, lack of exercise, exposure to cold, and various emotional causes.

9. *Ventrosuspension:* "An incision is made through the abdominal wall in the median line just above the symphysis pubis and extending upward for a distance of two inches. The index and middle fingers of the left hand are passed into the peritoneal cavity and gently inserted between the uterus and the rectum. The adhesions are then carefully separated and the fundus of the uterus lifted forward into its normal position. The peritoneum at the lower angle of the wound is seized with hemostatic forceps and drawn into the incision and the first suspension suture introduced close to its divided edge on the left side. The index and middle fingers of the left hand are then passed into the abdominal cavity and the uterus securely held while the suture is passed through the fundus. The suture is now introduced into the fundus directly on a line dividing the uterus transversely into two equal halves and buried one-quarter of an inch deep in the uterine tissue with a distance of about half an inch between the points of entrance and exit. The uterus is then released by the fingers of the left hand and the suture passed through the peritoneum opposite to its point of entrance. The second suture is now passed through the peritoneum on the left side one-quarter of an inch above the first suture. It is then passed through the fundus about one-quarter of an inch behind the first suture, and finally through the peritoneum opposite to its point of en-

trance. It is not necessary to hold the fundus between the fingers while the second suture is introduced, as the uterus can be easily controlled by making traction upon the free ends of the first suture. After both sutures have been introduced their free ends are seized with forceps and placed on each side of the abdominal incision. The through-and-through suture closing the abdominal incision are introduced and suspension sutures tied. The first three sutures closing the incision at the lower angle of the wound must be introduced so as to pass completely under the peritoneum at its points of attachment with the fundus, otherwise the weight of the uterus will cause stripping and a large dead space will result which will eventually become filled with serum or blood and suppurate. After all of the incision sutures are introduced the suspension sutures are drawn taut so as to take out the slack and bring the fundus of the uterus up against the peritoneum. The sutures are then tied and their free ends cut off close to the knots. The abdomen is closed and the wound dressed in the usual manner. The fascia is first united with a continuous suture of catgut and the wound then closed by tying the through-and-through sutures. The sutures in the lower angle of the wound are tied first, and special care must be taken to remove the slack and bring the peritoneum, at its points of attachment with the fundus, snugly against the abdominal wall."—(Ashton's *Gynecology.*)

10. The following symptoms may follow retroversion of the uterus: Backache, bearing-down pains, a feeling of pressure in the pelvis, constipation, hemorrhoids, frequent or painful urination, leucorrhea, menstrual disturbances, as dysmenorrhea or menorrhagia, sterility; there may also be *general symptoms*, as headache, indigestion, nausea, anorexia, neurasthenia, and general malaise.
